## Introduction ${ }^{1}$

### 1.1 Introduction

The development of algorithms for the fast computation of the Discrete Fourier Transform in the last 30 years originated with the radix 2 Cooley-Tukey FFT and the theory and variety of FFTs has grown significantly since then. Most of the work has focused on FFTs whose sizes are composite, for the algorithms depend on the ability to factor the length of the data sequence, so that the transform can be found by taking the transform of smaller lengths. For this reason, algorithms for prime length transforms are building blocks for many composite length FFTs - the maximum length and the variety of lengths of a PFA or WFTA algorithm depend upon the availability of prime length FFT modules. As such, prime length Fast Fourier Transforms are a special, important and difficult case.

Fast algorithms designed for specific short prime lengths have been developed and have been written as straight line code [9], [13]. These dedicated programs rely upon an observation made in Rader's paper [24] in which he shows that a prime $p$ length DFT can be found by performing a $p-1$ length circular convolution. Since the publication of that paper, Winograd had developed a theory of multiplicative complexity for transforms and designed algorithms for convolution that attain the minimum number of multiplications [38]. Although Winograd's algorithms are very efficient for small prime lengths, for longer lengths they require a large number of additions and the algorithms become very cumbersome to design. This has prevented the design of useful prime length FFT programs for lengths greater than 31. Although we have previously reported the design of programs for prime lengths greater than 31 [27] those programs required more additions than necessary and were long. Like the previously existing ones, they simply consisted of a long list of instructions and did not take advantage of the attainable common structures.

In this paper we describe a set of programs for circular convolution and prime length FFTs that are are short, possess great structure, share many computational procedures, and cover a large variety of lengths. Because the underlying convolution is decomposed into a set of disjoint operations they can be performed in parallel and this parallelism is made clear in the programs. Moreover, each of these independent operations is made up of a sequence of sub-operations of the form $I \otimes A \otimes I$ where $\otimes$ denotes the Kronecker product. These operations can be implemented as vector/parallel operations [34]. Previous programs for prime length FFTs do not have these features: they consist of straight line code and are not amenable to vector/parallel implementations.

We have also developed a program that automatically generates these programs for circular convolution and prime length DFTs. This code generating program requires information only about a set of modules for computing cyclotomic convolutions. We compute these non-circular convolutions by computing a linear convolution and reducing the result. Furthermore, because these linear convolution algorithms can be built from smaller ones, the only modules needed are ones for the linear convolution of prime length sequences. It turns out that with linear convolution algorithms for only the lengths 2 and 3 , we can generate a wide

[^0]variety of prime length FFT algorithms. In addition, the code we generate is made up of calls to a relatively small set of functions. Accordingly, the subroutines can be designed and optimized to specifically suit a given architecture.

The programs we describe use Rader's conversion of a prime point DFT into a circular convolution, but this convolution we compute using the split nesting algorithm [20]. As Stasinski notes [31], this yields algorithms possessing greater structure and simpler programs and doesn't generally require more computation.

### 1.1.1 On the Row-Column Method

In computing the DFT of an $n=n_{1} n_{2}$ point sequence where $n_{1}$ and $n_{2}$ are relatively prime, a row-column method can be employed. That is, if an $n_{1} \times n_{2}$ array is appropriately formed from the $n$ point sequence, then its DFT can be computed by computing the DFT of the rows and by then computing the DFT of the columns. The separability of the DFT makes this possible. It should be mentioned, however, that in at least two papers [31], [15] it is mistakenly assumed that the row-column method can also be applied to convolution. Unfortunately, the convolution of two sequences can not be found by forming two arrays, by convolving their rows, and by then convolving their columns. This misunderstanding about the separability of convolution also appears in [3] where the author incorrectly writes a diagonal matrix of a bilinear form as a Kronecker product. If it were a Kronecker product, then there would indeed exist a row-column method for convolution.

Earlier reports on this work were published in the conference proceedings [27], [28], [29] and a fairly complete report was published in the IEEE Transaction on Signal Processing [30]. Some parts of this approach appear in the Connexions book, Fast Fourier Transforms ${ }^{2}$. This work is built on and an extension of that in [29] which is also in the Connexions Technical Report ${ }^{3}$.

## Chapter 2

## Preliminaries

### 2.1 Preliminaries

Because we compute prime point DFTs by converting them in to circular convolutions, most of this and the next section is devoted to an explanation of the split nesting convolution algorithm. In this section we introduce the various operations needed to carry out the split nesting algorithm. In particular, we describe the prime factor permutation that is used to convert a one-dimensional circular convolution into a multidimensional one. We also discuss the reduction operations needed when the Chinese Remainder Theorem for polynomials is used in the computation of convolution. The reduction operations needed for the split nesting algorithm are particularly well organized. We give an explicit matrix description of the reduction operations and give a program that implements the action of these reduction operations.

The presentation relies upon the notions of similarity transformations, companion matrices and Kronecker products. With them, we describe the split nesting algorithm in a manner that brings out its structure. We find that when companion matrices are used to describe convolution, the reduction operations block diagonalizes the circular shift matrix.

The companion matrix of a monic polynomial, $M(s)=m_{0}+m_{1} s+\cdots+m_{n-1} s^{n-1}+s^{n}$ is given by

$$
C_{M}=\left[\begin{array}{cccc} 
& & & -m_{0} 1  \tag{2.1}\\
1 & & & -m_{1} \\
& \ddots & & \vdots \\
& & 1 & -m_{n-1}
\end{array}\right]
$$

Its usefulness in the following discussion comes from the following relation which permits a matrix formulation of convolution. Let

$$
\begin{align*}
X(s) & =x_{0}+x_{1} s+\cdots x_{n-1} s^{n-1} \\
H(s) & =h_{0}+h_{1} s+\cdots h_{n-1} s^{n-1}  \tag{2.2}\\
Y(s) & =y_{0}+y_{1} s+\cdots y_{n-1} s^{n-1} \\
M(s) & =m_{0}+m_{1} s+\cdots m_{n-1} s^{n-1}+s^{n}
\end{align*}
$$

Then

$$
\begin{equation*}
Y(s)=<H(s) X(s)>_{M(s)} \Leftrightarrow y=\left(\sum_{k=0}^{n-1} h_{k} C_{M}^{k}\right) x \tag{2.3}
\end{equation*}
$$

[^2]where $y=\left(y_{0}, \cdots, y_{n-1}\right)^{t}, x=\left(x_{0}, \cdots, x_{n-1}\right)^{t}$, and $C_{M}$ is the companion matrix of $M(s)$. In (2.3), we say $y$ is the convolution of $x$ and $h$ with respect to $M(s)$. In the case of circular convolution, $M(s)=s^{n}-1$ and $C_{s^{n}-1}$ is the circular shift matrix denoted by $S_{n}$,
\[

S_{n}=\left[$$
\begin{array}{llll} 
& & & 1  \tag{2.4}\\
1 & & & \\
& \ddots & & \\
& & 1 &
\end{array}
$$\right]
\]

Notice that any circulant matrix can be written as $\sum_{k} h_{k} S_{n}^{k}$.
Similarity transformations can be used to interpret the action of some convolution algorithms. If $C_{M}=T^{-1} A T$ for some matrix $T\left(C_{M}\right.$ and $A$ are similar, denoted $\left.C_{M} \sim A\right)$, then (2.3) becomes

$$
\begin{equation*}
y=T^{-1}\left(\sum_{k=0}^{n-1} h_{k} A^{k}\right) T x . \tag{2.5}
\end{equation*}
$$

That is, by employing the similarity transformation given by $T$ in this way, the action of $S_{n}^{k}$ is replaced by that of $A^{k}$. Many circular convolution algorithms can be understood, in part, by understanding the manipulations made to $S_{n}$ and the resulting new matrix $A$. If the transformation $T$ is to be useful, it must satisfy two requirements: (1) $T x$ must be simple to compute, and (2) $A$ must have some advantageous structure. For example, by the convolution property of the DFT, the DFT matrix $F$ diagonalizes $S_{n}$,

$$
S_{n}=F^{-1}\left[\begin{array}{cccc}
w^{0} & & &  \tag{2.6}\\
& w^{1} & & \\
& & \ddots & \\
& & & w^{n-1}
\end{array}\right] F
$$

so that it diagonalizes every circulant matrix. In this case, $T x$ can be computed by using an FFT and the structure of $A$ is the simplest possible. So the two above mentioned conditions are met.

The Winograd Structure can be described in this manner also. Suppose $M(s)$ can be factored as $M(s)=M_{1}(s) M_{2}(s)$ where $M_{1}$ and $M_{2}$ have no common roots, then $C_{M} \sim\left(C_{M_{1}} \oplus C_{M_{2}}\right)$ where $\oplus$ denotes the matrix direct sum. Using this similarity and recalling (2.3), the original convolution is decomposed into disjoint convolutions. This is, in fact, a statement of the Chinese Remainder Theorem for polynomials expressed in matrix notation. In the case of circular convolution, $s^{n}-1=\prod_{d \mid n} \Phi_{d}(s)$, so that $S_{n}$ can be transformed to a block diagonal matrix,

$$
S_{n} \sim\left[\begin{array}{cccc}
C_{\Phi_{1}} & & &  \tag{2.7}\\
& C_{\Phi_{d}} & & \\
& & \ddots & \\
& & & C_{\Phi_{n}}
\end{array}\right]=\left(\underset{d \mid n}{\oplus C_{\Phi_{d}}}\right)
$$

where $\Phi_{d}(s)$ is the $d^{t h}$ cyclotomic polynomial. In this case, each block represents a convolution with respect to a cyclotomic polynomial, or a 'cyclotomic convolution'. Winograd's approach carries out these cyclotomic convolutions using the Toom-Cook algorithm. Note that for each divisor, $d$, of $n$ there is a corresponding block on the diagonal of size $\phi(d)$, for the degree of $\Phi_{d}(s)$ is $\phi(d)$ where $\phi(\cdot)$ is the Euler totient function. This method is good for short lengths, but as $n$ increases the cyclotomic convolutions become cumbersome, for as the number of distinct prime divisors of $d$ increases, the operation described by $\sum_{k} h_{k}\left(C_{\Phi_{d}}\right)^{k}$ becomes more difficult to implement.

The Agarwal-Cooley Algorithm utilizes the fact that

$$
\begin{equation*}
S_{n}=P^{t}\left(S_{n_{1}} \otimes S_{n_{2}}\right) P \tag{2.8}
\end{equation*}
$$

where $n=n_{1} n_{2},\left(n_{1}, n_{2}\right)=1$ and $P$ is an appropriate permutation [1]. This converts the one dimensional circular convolution of length $n$ to a two dimensional one of length $n_{1}$ along one dimension and length $n_{2}$ along the second. Then an $n_{1}$-point and an $n_{2}$-point circular convolution algorithm can be combined to obtain an $n$-point algorithm. In polynomial notation, the mapping accomplished by this permutation $P$ can be informally indicated by

$$
\begin{equation*}
Y(s)=<X(s) H(s)>_{s^{n}-1} \stackrel{P}{\Leftrightarrow} Y(s, t)=<X(s, t) H(s, t)>_{s^{n_{1}-1, t^{n_{2}}-1}} . \tag{2.9}
\end{equation*}
$$

It should be noted that (2.8) implies that a circulant matrix of size $n_{1} n_{2}$ can be written as a block circulant matrix with circulant blocks.

The Split-Nesting algorithm [21] combines the structures of the Winograd and Agarwal-Cooley methods, so that $S_{n}$ is transformed to a block diagonal matrix as in (2.7),

$$
\begin{equation*}
S_{n} \sim \underset{d \mid n}{\oplus} \Psi(d) \tag{2.10}
\end{equation*}
$$

Here $\Psi(d)=\otimes_{p \mid d, p \in \mathcal{P}} C_{\Phi_{H_{d}(p)}}$ where $H_{d}(p)$ is the highest power of $p$ dividing $d$, and $\mathcal{P}$ is the set of primes.

## Example 2.1

$$
S_{45} \sim\left[\begin{array}{llllll}
1 & & & & &  \tag{2.11}\\
& C_{\Phi_{3}} & & & & \\
& & C_{\Phi_{9}} & & & \\
& & & C_{\Phi_{5}} & & \\
& & & & C_{\Phi_{3}} \otimes C_{\Phi_{5}} & \\
& & & & & C_{\Phi_{9}} \otimes C_{\Phi_{5}}
\end{array}\right]
$$

In this structure a multidimensional cyclotomic convolution, represented by $\Psi(d)$, replaces each cyclotomic convolution in Winograd's algorithm (represented by $C_{\Phi_{d}}$ in (2.7). Indeed, if the product of $b_{1}, \cdots, b_{k}$ is $d$ and they are pairwise relatively prime, then $C_{\Phi_{d}} \sim C_{\Phi_{b_{1}}} \otimes \cdots \otimes C_{\Phi_{b_{k}}}$. This gives a method for combining cyclotomic convolutions to compute a longer circular convolution. It is like the Agarwal-Cooley method but requires fewer additions [21].

### 2.2 Prime Factor Permutations

One can obtain $S_{n_{1}} \otimes S_{n_{2}}$ from $S_{n_{1} n_{2}}$ when $\left(n_{1}, n_{2}\right)=1$, for in this case, $S_{n}$ is similar to $S_{n_{1}} \otimes S_{n_{2}}, n=n_{1} n_{2}$. Moreover, they are related by a permutation. This permutation is that of the prime factor FFT algorithms and is employed in nesting algorithms for circular convolution [1], [18]. The permutation is described by Zalcstein [40], among others, and it is his description we draw on in the following.

Let $n=n_{1} n_{2}$ where $\left(n_{1}, n_{2}\right)=1$. Define $e_{k},(0 \leq k \leq n-1)$, to be the standard basis vector, $(0, \cdots, 0,1,0, \cdots, 0)^{t}$, where the 1 is in the $k^{t h}$ position. Then, the circular shift matrix, $S_{n}$, can be described by

$$
\begin{equation*}
S_{n} e_{k}=e_{<k+1>_{n}} \tag{2.12}
\end{equation*}
$$

Note that, by inspection,

$$
\begin{equation*}
\left(S_{n_{2}} \otimes S_{n_{1}}\right) e_{a+n_{1} b}=e_{<a+1>_{n_{1}}+n_{1}}^{<b+1>_{n_{2}}} \tag{2.13}
\end{equation*}
$$

where $0 \leq a \leq n_{1}-1$ and $0 \leq b \leq n_{2}-1$. Because $n_{1}$ and $n_{2}$ are relatively prime a permutation matrix $P$ can be defined by

$$
\begin{equation*}
P e_{k}=e<k>_{n_{1}}+n_{1}<k>_{n_{2}} \tag{2.14}
\end{equation*}
$$

With this $P$,

$$
\begin{array}{rlc}
P S_{n} e_{k} & = & P e_{<k+1>_{n}} \\
& = & e \ll k+1>_{n}>_{n_{1}}+n_{1} \ll k+1>_{n}>_{n_{2}}  \tag{2.15}\\
& = & e<k+1>_{n_{1}}+n_{1}<k+1>_{n_{2}}
\end{array}
$$

and

$$
\begin{align*}
\left(S_{n_{2}} \otimes S_{n_{1}}\right) P e_{k} & =\left(S_{n_{2}} \otimes S_{n_{1}}\right) e<k>_{n_{1}}+n_{1}<k>_{n_{2}}  \tag{2.16}\\
& =\quad e<k+1>_{n_{1}}+n_{1}<k+1>_{n_{2}}
\end{align*}
$$

Since $P S_{n} e_{k}=\left(S_{n_{2}} \otimes S_{n_{1}}\right) P e_{k}$ and $P^{-1}=P^{t}$, one gets, in the multi-factor case, the following.

## Lemma 2.1:

If $n=n_{1} \cdots n_{k}$ and $n_{1}, \ldots, n_{k}$ are pairwise relatively prime, then $S_{n}=P^{t}\left(S_{n_{k}} \otimes \cdots \otimes S_{n_{1}}\right) P$ where $P$ is the permutation matrix given by $P e_{k}=e<k>_{n_{1}+n_{1}}<k>_{n_{2}}+\cdots+n_{1} \cdots n_{k-1}<k>_{n_{k}}$.
This useful permutation will be denoted here as $P_{n_{k}, \cdots, n_{1}}$. If $n=p_{1}^{e_{1}} p_{2}^{e_{2}} \cdots p_{k}^{e_{k}}$ then this permutation
 $S_{n}=P_{n_{1}, \cdots, n_{k}}^{t}\left(\stackrel{k}{\otimes} S_{i=1}^{\otimes} p_{p_{i}}\right) P_{n_{1}, \cdots, n_{k}}$.

It is quite simple to show that

$$
\begin{equation*}
P_{a, b, c}=\left(I_{a} \otimes P_{b, c}\right) P_{a, b c}=\left(P_{a, b} \otimes I_{c}\right) P_{a b, c} \tag{2.17}
\end{equation*}
$$

In general, one has

$$
\begin{equation*}
P_{n_{1}, \cdots, n_{k}}=\prod_{i=2}^{k}\left(P_{n_{1} \cdots n_{i-1}, n_{i}} \otimes I_{n_{i+1} \cdots n_{k}}\right) \tag{2.18}
\end{equation*}
$$

A Matlab function for $P_{a, b} \otimes I_{s}$ is pfp 2 I() in one of the appendices. This program is a direct implementation of the definition. In a paper by Templeton [32], another method for implementing $P_{a, b}$, without 'if' statements, is given. That method requires some precalculations, however. A function for $P_{n_{1}, \cdots, n_{k}}$ is pfp(). It uses (2.18) and calls pfp2I () with the appropriate arguments.

### 2.3 Reduction Operations

The Chinese Remainder Theorem for polynomials can be used to decompose a convolution of two sequences (the polynomial product of two polynomials evaluated modulo a third polynomial) into smaller convolutions (smaller polynomial products) [39]. The Winograd $n$ point circular convolution algorithm requires that polynomials are reduced modulo the cyclotomic polynomial factors of $s^{n}-1, \Phi_{d}(s)$ for each $d$ dividing $n$.

When $n$ has several prime divisors the reduction operations become quite complicated and writing a program to implement them is difficult. However, when $n$ is a prime power, the reduction operations are very structured and can be done in a straightforward manner. Therefore, by converting a one-dimensional convolution to a multi-dimensional one, in which the length is a prime power along each dimension, the split nesting algorithm avoids the need for complicated reductions operations. This is one advantage the split nesting algorithm has over the Winograd algorithm.

By applying the reduction operations appropriately to the circular shift matrix, we are able to obtain a block diagonal form, just as in the Winograd convolution algorithm. However, in the split nesting algorithm, each diagonal block represents multi-dimensional cyclotomic convolution rather than a one-dimensional one. By forming multi-dimensional convolutions out of one-dimensional ones, it is possible to combine algorithms for smaller convolutions (see the next section). This is a second advantage split nesting algorithm has over the Winograd algorithm. The split nesting algorithm, however, generally uses more than the minimum number of multiplications.

Below we give an explicit matrix description of the required reduction operations, give a program that implements them, and give a formula for the number of additions required. (No multiplications are needed.)

First, consider $n=p$, a prime. Let

$$
\begin{equation*}
X(s)=x_{0}+x_{1} s+\cdots+x_{p-1} s^{p-1} \tag{2.19}
\end{equation*}
$$

and recall $s^{p}-1=(s-1)\left(s^{p-1}+s^{p-2}+\cdots+s+1\right)=\Phi_{1}(s) \Phi_{p}(s)$. The residue $<X(s)>_{\Phi_{1}(s)}$ is found by summing the coefficients of $X(s)$. The residue $<X(s)>_{\Phi_{p}(s)}$ is given by $\sum_{k=0}^{p-2}\left(x_{k}-x_{p-1}\right) s^{k}$. Define $R_{p}$ to be the matrix that reduces $X(s)$ modulo $\Phi_{1}(s)$ and $\Phi_{p}(s)$, such that if $X_{0}(s)=<X(s)>_{\Phi_{1}(s)}$ and $X_{1}(s)=<X(s)>_{\Phi_{p}(s)}$ then

$$
\left[\begin{array}{c}
X_{0}  \tag{2.20}\\
X_{1}
\end{array}\right]=R_{p} X
$$

where $X, X_{0}$ and $X_{1}$ are vectors formed from the coefficients of $X(s), X_{0}(s)$ and $X_{1}(s)$. That is,

$$
R_{p}=\left[\begin{array}{ccccc}
1 & 1 & 1 & 1 & 1  \tag{2.21}\\
1 & & & & -1 \\
& 1 & & & -1 \\
& & 1 & & -1 \\
& & & 1 & -1
\end{array}\right]
$$

so that $R_{p}=\left[\begin{array}{c}1_{-1} \\ G_{p}\end{array}\right]$ where $G_{p}$ is the $\Phi_{p}(s)$ reduction matrix of size $(p-1) \times p$. Similarly, let $X(s)=$ $x_{0}+x_{1} s+\cdots+x_{p^{e-1}} s^{p^{e-1}}$ and define $R_{p^{e}}$ to be the matrix that reduces $X(s)$ modulo $\Phi_{1}(s), \Phi_{p}(s), \ldots$, $\Phi_{p^{e}}(s)$ such that

$$
\left[\begin{array}{c}
X_{0}  \tag{2.22}\\
X_{1} \\
\vdots \\
X_{e}
\end{array}\right]=R_{p^{e}} X,
$$

where as above, $X, X_{0}, \ldots, X_{e}$ are the coefficients of $X(s),<X(s)>_{\Phi_{1}(s)}, \ldots,<X(s)>_{\Phi_{p^{e}}(s)}$.
It turns out that $R_{p^{e}}$ can be written in terms of $R_{p}$. Consider the reduction of $X(s)=x_{0}+\cdots+x_{8} s^{8}$ by $\Phi_{1}(s)=s-1, \Phi_{3}(s)=s^{2}+s+1$, and $\Phi_{9}(s)=s^{6}+s^{3}+1$. This is most efficiently performed by reducing $X(s)$ in two steps. That is, calculate $X^{\prime}(s)=<X(s)>_{s^{3}-1}$ and $X_{2}(s)=<X(s)>_{s^{6}+s^{3}+1}$. Then calculate $X_{0}(s)=<X^{\prime}(s)>_{s-1}$ and $X_{1}(s)=<X^{\prime}(s)>_{s^{2}+s+1}$. In matrix notation this becomes

$$
\left[\begin{array}{l}
X^{\prime}  \tag{2.23}\\
X_{2}
\end{array}\right]=\left[\begin{array}{rrr}
I_{3} & I_{3} & I_{3} \\
I_{3} & & -I_{3} \\
& I_{3} & -I_{3}
\end{array}\right] X \text { and }\left[\begin{array}{l}
X_{0} \\
X_{1}
\end{array}\right]=\left[\begin{array}{rrr}
1 & 1 & 1 \\
1 & & -1 \\
& 1 & -1
\end{array}\right] X^{\prime}
$$

Together these become

$$
\left[\begin{array}{l}
X_{0}  \tag{2.24}\\
X_{1} \\
X_{2}
\end{array}\right]=\left[\begin{array}{lll}
R_{3} & & \\
& I_{3} & \\
& & I_{3}
\end{array}\right]\left[\begin{array}{rrr}
I_{3} & I_{3} & I_{3} \\
I_{3} & & -I_{3} \\
& I_{3} & -I_{3}
\end{array}\right] X
$$

or

$$
\left[\begin{array}{l}
X_{0}  \tag{2.25}\\
X_{1} \\
X_{2}
\end{array}\right]=\left(R_{3} \oplus I_{6}\right)\left(R_{3} \otimes I_{3}\right) X
$$

so that $R_{9}=\left(R_{3} \oplus I_{6}\right)\left(R_{3} \otimes I_{3}\right)$ where $\oplus$ denotes the matrix direct sum. Similarly, one finds that $R_{27}=$ $\left(R_{3} \oplus I_{24}\right)\left(\left(R_{3} \otimes I_{3}\right) \oplus I_{18}\right)\left(R_{3} \otimes I_{9}\right)$. In general, one has the following.

## Lemma 2.2:

$R_{p^{e}}$ is a $p^{e} \times p^{e}$ matrix given by $R_{p^{e}}=\prod_{k=0}^{e-1}\left(\left(R_{p} \otimes I_{p^{k}}\right) \oplus I_{p^{e}-p^{k+1}}\right)$ and can be implemented with $2\left(p^{e}-1\right)$ additions.
The following formula gives the decomposition of a circular convolution into disjoint non-circular convolutions when the number of points is a prime power.

$$
\begin{align*}
R_{p^{e}} S_{p^{e}} R_{p^{e}}^{-1} & =\left[\begin{array}{llll}
1 & & & \\
& C_{\Phi_{p}} & & \\
& & \ddots & \\
& & & C_{\Phi_{p^{e}}}
\end{array}\right]  \tag{2.26}\\
& =\begin{array}{lll}
\stackrel{e}{i=0} C_{\Phi_{p^{i}}}
\end{array}
\end{align*}
$$

Example 2.2

$$
R_{9} S_{9} R_{9}^{-1}=\left[\begin{array}{lll}
1 & &  \tag{2.27}\\
& C_{\Phi_{3}} & \\
& & C_{\Phi_{9}}
\end{array}\right]
$$

It turns out that when $n$ is not a prime power, the reduction of polynomials modulo the cyclotomic polynomial $\Phi_{n}(s)$ becomes complicated, and with an increasing number of prime factors, the complication increases. Recall, however, that a circular convolution of length $p_{1}^{e_{1}} \cdots p_{k}^{e_{k}}$ can be converted (by an appropriate permutation) into a $k$ dimensional circular convolution of length $p_{i}^{e_{i}}$ along dimension $i$. By employing this one-dimensional to multi-dimensional mapping technique, one can avoid having to perform polynomial reductions modulo $\Phi_{n}(s)$ for non-prime-p ower $n$.

The prime factor permutation discussed previously is the permutation that converts a one-dimensional circular convolution into a multi-dimensional one. Again, we can use the Kronecker product to represent this. In this case, the reduction operations are applied to each matrix in the following way:

$$
\begin{equation*}
T\left(S_{p_{1}^{e_{1}}} \otimes \cdots \otimes S_{p_{k}^{e_{k}}}\right) T^{-1}=\left(\oplus_{i=0}^{e_{1}} C_{\Phi_{p_{1}^{i}}}\right) \otimes \cdots \otimes\left(\oplus_{i=0}^{e_{k}} C_{\Phi_{p_{k}^{i}}}\right) \tag{2.28}
\end{equation*}
$$

where

$$
\begin{equation*}
T=R_{p_{1}^{e_{1}}} \otimes \cdots \otimes R_{p_{k}^{e_{k}}} \tag{2.29}
\end{equation*}
$$

## Example 2.3

$$
T\left(S_{9} \otimes S_{5}\right) T^{-1}=\left[\begin{array}{lll}
1 & &  \tag{2.30}\\
& C_{\Phi_{3}} & \\
& & C_{\Phi_{9}}
\end{array}\right] \otimes\left[\begin{array}{ll}
1 & \\
& C_{\Phi_{5}}
\end{array}\right]
$$

where $T=R_{9} \otimes R_{5}$.
The matrix $R_{p_{1}^{e_{1}}} \otimes \cdots \otimes R_{p_{k}^{e_{k}}}$ can be factored using a property of the Kronecker product. Notice that $(A \otimes B)=(A \otimes I)(I \otimes B)$, and $(A \otimes B \otimes C)=(A \otimes I)(I \otimes B \otimes I)(I \otimes C)$ (with appropriate dimensions) so that one gets

$$
\begin{equation*}
\stackrel{k}{\stackrel{k}{\otimes}} R_{p_{i}^{e_{i}}}=\prod_{i=1}^{k}\left(I_{m_{i}} \otimes R_{p_{i}^{e_{i}}} \otimes I_{n_{i}}\right), \tag{2.31}
\end{equation*}
$$

where $m_{i}=\prod_{j=1}^{i-1} p_{j}^{e_{j}}, n_{i}=\prod_{j=i+1}^{k} p_{j}^{e_{j}}$ and where the empty product is taken to be 1 . This factorization shows that $T$ can be implemented basically by implementing copies of $R_{p^{e}}$. There are many variations on this factorization as explained in [35]. That the various factorization can be interpreted as vector or parallel implementations is also explained in [35].

## Example 2.4

$$
\begin{equation*}
R_{9} \otimes R_{5}=\left(R_{9} \otimes I_{5}\right)\left(I_{9} \otimes R_{5}\right) \tag{2.32}
\end{equation*}
$$

and

$$
\begin{equation*}
R_{9} \otimes R_{25} \otimes R_{7}=\left(R_{9} \otimes I_{175}\right)\left(I_{9} \otimes R_{25} \otimes I_{7}\right)\left(I_{225} \otimes R_{7}\right) \tag{2.33}
\end{equation*}
$$

When this factored form of $\otimes R_{n_{i}}$ or any of the variations alluded to above, is used, the number of additions incurred is given by

$$
\begin{align*}
\sum_{i=1}^{k} \frac{N}{p_{i}^{e_{i}}} \mathcal{A}\left(R_{p_{i}^{e_{i}}}\right) & =\sum_{i=1}^{k} \frac{N}{p_{i}^{e_{i}}} 2\left(p_{i}^{e_{i}}-1\right) \\
& =2 N \sum_{i=1}^{k} 1-\frac{1}{p_{i}^{e_{i}}}  \tag{2.34}\\
& =2 N\left(k-\sum_{i=1}^{k} \frac{1}{p_{i}^{e_{i}}}\right)
\end{align*}
$$

where $N=p_{1}^{e_{1}} \cdots p_{k}^{e_{k}}$.
Although the use of operations of the form $R_{p_{1}^{e_{1}}} \otimes \cdots \otimes R_{p_{k}^{e_{k}}}$ is simple, it does not exactly separate the circular convolution into smaller disjoint convolutions. In other words, its use does not give rise in (2.28) and (2.30) to block diagonal matrices whose diagonal blocks are the form $\otimes_{i} C_{\Phi_{p_{i}}}$. However, by reorganizing the arrangement of the operations we can obtain the block diagonal form we seek.

First, suppose $A, B$ and $C$ are matrices of sizes $a \times a, b \times b$ and $c \times c$ respectively. If

$$
T B T^{-1}=\left[\begin{array}{ll}
B_{1} &  \tag{2.35}\\
& B_{2}
\end{array}\right]
$$

where $B_{1}$ and $B_{2}$ are matrices of sizes $b_{1} \times b_{1}$ and $b_{2} \times b_{2}$, then

$$
Q(A \otimes B \otimes C) Q^{-1}=\left[\begin{array}{c}
A \otimes B_{1} \otimes C  \tag{2.36}\\
A \otimes B_{2} \otimes C
\end{array}\right]
$$

where

$$
Q=\left[\begin{array}{c}
I_{a} \otimes T\left(1: b_{1},:\right) \otimes I_{c}  \tag{2.37}\\
I_{a} \otimes T\left(b_{1}+1: b,:\right) \otimes I_{c}
\end{array}\right]
$$

Here $T\left(1: b_{1},:\right)$ denotes the first $b_{1}$ rows and all the columns of $T$ and similarly for $T\left(b_{1}+1: b,:\right)$. Note that

$$
\left[\begin{array}{cc}
A \otimes B_{1} \otimes C &  \tag{2.38}\\
& A \otimes B_{2} \otimes C
\end{array}\right] \neq A \otimes\left[\begin{array}{ll}
B_{1} & \\
& B_{2}
\end{array}\right] \otimes C .
$$

That these two expressions are not equal explains why the arrangement of operations must be reorganized in order to obtain the desired block diagonal form. The appropriate reorganization is described by the expression in (2.37). Therefore, we must modify the transformation of (2.28) appropriately. It should be noted that this reorganization of operations does not change their computational cost. It is still given by (2.34).

For example, we can use this observation and the expression in (2.37) to arrive at the following similarity transformation:

$$
Q\left(S_{p_{1}} \otimes S_{p_{2}}\right) Q^{-1}=\left[\begin{array}{llll}
1 & & &  \tag{2.39}\\
& C_{\Phi_{p_{1}}} & & \\
& & C_{\Phi_{p_{2}}} & \\
& & & C_{\Phi_{p_{1}}} \otimes C_{\Phi_{p_{2}}}
\end{array}\right]
$$

where

$$
Q=\left[\begin{array}{c}
I_{p_{1}} \otimes 1_{-\mathrm{p}_{2}}^{t}  \tag{2.40}\\
I_{p_{1}} \otimes G_{p_{2}}
\end{array}\right]\left(R_{p_{1}} \otimes I_{p_{2}}\right)
$$

$1_{-\mathrm{p}}$ is a column vector of $p 1$ 's

$$
1_{-\mathrm{p}}=\left[\begin{array}{llll}
1 & 1 & \cdots & 1 \tag{2.41}
\end{array}\right]^{t}
$$

and $G_{p}$ is the $(p-1) \times p$ matrix:

$$
G_{p}=\left[\begin{array}{ccccc}
1 & & & & -1  \tag{2.42}\\
& 1 & & & -1 \\
& & \ddots & & \vdots \\
& & & 1 & -1
\end{array}\right]=\left[I_{p-1}-\underline{1}_{p-1}\right]
$$

In general we have

$$
\begin{equation*}
R\left(S_{p_{1}^{e_{1}}} \otimes \cdots \otimes S_{p_{k}^{e_{k}}}\right) R^{-1}=\underset{d \mid n}{\oplus} \Psi(d) \tag{2.43}
\end{equation*}
$$

where $R=R_{p_{1}^{e_{1}}, \cdots, p_{k}^{e_{k}}}$ is given by

$$
\begin{equation*}
R_{p_{1}^{e_{1}}, \ldots, p_{k}^{e_{k}}}=\prod_{i=k}^{1} Q\left(m_{i}, p_{i}^{e_{i}}, n_{i}\right) \tag{2.44}
\end{equation*}
$$

with $m_{i}=\prod_{j=1}^{i-1} p_{j}^{e_{j}}, n_{i}=\prod_{j=i+1}^{k} p_{j}^{e_{j}}$ and

$$
Q\left(a, p^{e}, c\right)=\prod_{j=0}^{e-1}\left[\begin{array}{cc}
I_{a} \otimes 1_{-p}^{t} \otimes I_{c p^{j}} &  \tag{2.45}\\
I_{a} \otimes G_{p} \otimes I_{c p^{j}} & \\
& I_{a c\left(p^{e}-p^{j+1}\right)}
\end{array}\right]
$$

$1_{-\mathrm{p}}$ and $G_{p}$ are as given in (2.41) and (2.42).

## Example 2.5

$$
R\left(S_{9} \otimes S_{5}\right) R^{-1}=\left[\begin{array}{cccccc}
1 & & & & &  \tag{2.46}\\
& C_{\Phi_{3}} & & & & \\
& & C_{\Phi_{9}} & & & \\
& & & C_{\Phi_{5}} & & \\
& & & & C_{\Phi_{3}} \otimes C_{\Phi_{5}} & \\
& & & & & C_{\Phi_{9}} \otimes C_{\Phi_{5}}
\end{array}\right]
$$

where

$$
\begin{array}{rlc}
R & = & R_{9,5}  \tag{2.47}\\
& = & Q(9,5,1) Q(1,9,5)
\end{array}
$$

and $R$ can be implemented with 152 additions.
Notice the distinction between this example and example "Reduction Operations" (Section 2.3: Reduction Operations). In example "Reduction Operations" (Section 2.3: Reduction Operations) we obtained from $S_{9} \otimes S_{5}$ a Kronecker product of two block diagonal matrices, but here we obtained a block diagonal matrix whose diagonal blocks are the Kronecker product of cyclotomic companion matrices. Each block in (2.46) represents a multi-dimensional cyclotomic convolution.

A Matlab program that carries out the operation $R_{p_{1}^{e_{1}}, \ldots, p_{k}^{e_{k}}}$ in (2.43) is KRED().

```
    function x = KRED(P,E,K,x)
% x = KRED(P,E,K,x);
% P : P = [P(1),...,P(K)];
% E : E = [E(K),...,E(K)];
for i = 1:K
    a = prod(P(1:i-1).^E(1:i-1));
    c = prod(P(i+1:K).^E(i+1:K));
    p = P(i);
    e = E(i);
    for j = e-1:-1:0
        x(1:a*c*(p^}(j+1)))= RED(p,a,c*(p^j),x(1:a*c*(p^(j+1))))
    end
end
```

It calls the Matlab program RED () .

```
    function y = RED(p,a,c,x)
% y = RED(p,a,c,x);
y = zeros(a*c*p,1);
for i = 0:c:(a-1)*c
    for j = 0:c-1
        y(i+j+1) = x(i*p+j+1);
```

```
        for k = 0:c:c*(p-2)
                        y(i+j+1) = y (i+j+1) + x (i*p+j+k+c+1);
            y(i*(p-1)+j+k+a*c+1) = x(i*p+j+k+1) - x(i*p+j+c*(p-1)+1);
        end
    end
end
```

These two Matlab programs are not written to run as fast as they could be. They are a 'naive' coding of $R_{p_{1}^{e_{1}}, \cdots, p_{k}^{e_{k}}}$ and are meant to serve as a basis for more efficient programs. In particular, the indexing and the loop counters can be modified to improve the efficiency. However, the modifications that minimize the overhead incurred by indexing operations depends on the programming language, the compiler and the computer used. These two programs are written with simple loop counters and complicated indexing operations so that appropriate modifications can be easily made.

### 2.3.1 Inverses

The inverse of $R_{p}$ has the form

$$
R_{p}^{-1}=\frac{1}{p}\left[\begin{array}{ccccc}
1 & p-1 & -1 & -1 & -1  \tag{2.48}\\
1 & -1 & p-1 & -1 & -1 \\
1 & -1 & -1 & p-1 & -1 \\
1 & -1 & -1 & -1 & p-1 \\
1 & -1 & -1 & -1 & -1
\end{array}\right]
$$

and

$$
\begin{equation*}
R_{p^{e}}^{-1}=\prod_{k=0}^{e-1}\left(\left(R_{p}^{-1} \otimes I_{p^{e-1-k}}\right) \oplus I_{p^{e}-p^{e-k}}\right) \tag{2.49}
\end{equation*}
$$

Because the inverse of $Q$ in (2.37) is given by

$$
\begin{equation*}
Q^{-1}=\left[I_{a} \otimes T^{-1}\left(:, 1: b_{1}\right) \otimes I_{c} \quad I_{a} \otimes T^{-1}\left(:, b_{1}+1: b\right) \otimes I_{c}\right] \tag{2.50}
\end{equation*}
$$

the inverse of the matrix $R$ described by eqs (2.43), (2.44) and (2.45) is given by

$$
\begin{equation*}
R^{-1}=\prod_{i=1}^{k} Q\left(m_{i}, p_{i}^{e_{i}}, n_{i}\right)^{-1} \tag{2.51}
\end{equation*}
$$

with $m_{i}=\prod_{j=1}^{i-1} p_{j}^{e_{j}}, n_{i}=\prod_{j=i+1}^{k} p_{j}^{e_{j}}$ and

$$
Q\left(a, p^{e}, c\right)^{-1}=\prod_{j=e-1}^{0}\left[\begin{array}{lll}
I_{a} \otimes 1_{-\mathrm{p}}^{t} \otimes I_{c p^{j}} & I_{a} \otimes V_{p} \otimes I_{c p^{j}} &  \tag{2.52}\\
& & I_{a c\left(p^{e}-p^{j+1}\right)}
\end{array}\right]
$$

where $V_{p}$ denotes the matrix in (2.48) without the first column. A Matlab program for $R^{t}$ is tKRED(), it calls the Matlab program tRED() . A Matlab program for $R^{-t}$ is $\operatorname{itKRED}()$, it calls the Matlab program itRED(). These programs all appear in one of the appendices.

## Chapter 3

## Bilinear Forms for Circular Convolution'

### 3.1 Bilinear Forms for Circular Convolution

A basic technique in fast algorithms for convolution is that of interpolation. That is, two polynomials are evaluated at some common points and these values are multiplied [4], [17], [22]. By interpolating these products, the product of the two original polynomials can be determined. In the Winograd short convolution algorithms, this technique is used and the common points of evaluation are the simple integers, 0,1 , and -1 . Indeed, the computational savings of the interpolation technique depends on the use of special points at which to interpolate. In the Winograd algorithm the computational savings come from the simplicity of the small integers. (As an algorithm for convolution, the FFT interpolates over the roots of unity.) This interpolation method is often called the Toom-Cook method and it is given by two matrices that describe a bilinear form.

We use bilinear forms to give a matrix formulation of the split nesting algorithm. The split nesting algorithm combines smaller convolution algorithms to obtain algorithms for longer lengths. We use the Kronecker product to explicitly describe the way in which smaller convolution algorithms are appropriately combined.

### 3.1.1 The Scalar Toom-Cook Method

First we consider the linear convolution of two $n$ point sequences. Recall that the linear convolution of $h$ and $x$ can be represented by a matrix vector product. When $n=3$ :

$$
\left[\begin{array}{lll}
h_{0} & &  \tag{3.1}\\
h_{1} & h_{0} & \\
h_{2} & h_{1} & h_{0} \\
& h_{2} & h_{1} \\
& & \\
& & \\
h_{2}
\end{array}\right]\left[\begin{array}{l}
x_{0} \\
x_{1} \\
x_{2}
\end{array}\right]
$$

This linear convolution matrix can be written as $h_{0} H_{0}+h_{1} H_{1}+h_{2} H_{2}$ where $H_{k}$ are clear.
The product $\sum_{k=0}^{n-1} h_{k} H_{k} x$ can be found using the Toom-Cook algorithm, an interpolation method.

[^3]Choose $2 n-1$ interpolation points, $i_{1}, \cdots, i_{2 n-1}$, and let $A$ and $C$ be matrices given by

$$
A=\left[\begin{array}{ccc}
i_{1}^{0} & \cdots & i_{1}^{n-1}  \tag{3.2}\\
& \vdots & \\
i_{2 n-1}^{0} & \cdots & i_{2 n-1}^{n-1}
\end{array}\right] \text { and } C=\left[\begin{array}{ccc}
i_{1}^{0} & \cdots & i_{1}^{2 n-2} \\
& \vdots & \\
i_{2 n-1}^{0} & \cdots & i_{2 n-1}^{2 n-2}
\end{array}\right]^{-1}
$$

That is, $A$ is a degree $n-1$ Vandermonde matrix and $C$ is the inverse of the degree $2 n-2$ Vandermonde matrix specified by the same points specifying $A$. With these matrices, one has

$$
\begin{equation*}
\sum_{k=0}^{n-1} h_{k} H_{k} x=C\{A h * A x\} \tag{3.3}
\end{equation*}
$$

where $*$ denotes point by point multiplication. The terms $A h$ and $A x$ are the values of $H(s)$ and $X(s)$ at the points $i_{1}, \cdots i_{2 n-1}$. The point by point multiplication gives the values $Y\left(i_{1}\right), \cdots, Y\left(i_{2 n-1}\right)$. The operation of $C$ obtains the coefficients of $Y(s)$ from its values at these points of evaluation. This is the bilinear form and it implies that

$$
\begin{equation*}
H_{k}=\operatorname{Cdiag}\left(A e_{k}\right) A \tag{3.4}
\end{equation*}
$$

## Example 3.1

If $n=2$, then equations (3.3) and (3.4) give

$$
\left[\begin{array}{cc}
h_{0} & 0  \tag{3.5}\\
h_{1} & h_{0} \\
0 & h_{1}
\end{array}\right] x=C\{A h * A x\}
$$

When the interpolation points are 0,1 , and -1 ,

$$
A=\left[\begin{array}{cc}
1 & 0  \tag{3.6}\\
1 & 1 \\
1 & -1
\end{array}\right] \quad \text { and } \quad C=\left[\begin{array}{ccc}
1 & 0 & 0 \\
0 & .5 & -.5 \\
-1 & .5 & .5
\end{array}\right]
$$

However, $A$ and $C$ do not need to be Vandermonde matrices as in (3.2). For example, see the two point linear convolution algorithm in the appendix. As long as $A$ and $C$ are matrices such that $H_{k}=\operatorname{Cdiag}\left(A e_{k}\right) A$, then the linear convolution of $x$ and $h$ is given by the bilinear form $y=C\{A h * A x\}$. More generally, as long as $A, B$ and $C$ are matrices satisfying $H_{k}=\operatorname{Cdiag}\left(B e_{k}\right) A$, then $y=C\{B h * A x\}$ computes the linear convolution of $h$ and $x$. For convenience, if $C\{A h * A x\}$ computes the $n$ point linear convolution of $h$ and $x$ (both $h$ and $x$ are $n$ point sequences), then we say " $A, B, C)$ describes a bilinear form for $n$ point linear convolution."

Similarly, we can write a bilinear form for cyclotomic convolution. Let $d$ be any positive integer and let $X(s)$ and $H(s)$ be polynomials of degree $\phi(d)-1$ where $\phi(\cdot)$ is the Euler totient function. If $A$, $B$ and $C$ are matrices satisfying $\left(C_{\Phi_{d}}\right)^{k}=\operatorname{Cdiag}\left(B e_{k}\right) A$ for $0 \leq k \leq \phi(d)-1$, then the coefficients of $Y(s)=<X(s) H(s)>_{\Phi_{d}(s)}$ are given by $y=C\{B h * A x\}$. As above, if $y=C\{B h * A x\}$ computes the $d$-cyclotomic convolution, then we say " $(A, B, C)$ describes a bilinear form for $\Phi_{d}(s)$ convolution."

But since $<X(s) H(s)>_{\Phi_{d}(s)}$ can be found by computing the product of $X(s)$ and $H(s)$ and reducing the result, a cyclotomic convolution algorithm can always be derived by following a linear convolution algorithm by the appropriate reduction operation: If $G$ is the appropriate reduction matrix and if $(A, B, F)$ describes a bilinear form for a $\phi(d)$ point linear convolution, then $(A, B, G F)$ describes a bilinear form for $\Phi_{d}(s)$ convolution. That is, $y=G F\{B h * A x\}$ computes the coefficients of $<X(s) H(s)>_{\Phi_{d}(s)}$.

### 3.1.2 Circular Convolution

By using the Chinese Remainder Theorem for polynomials, circular convolution can be decomposed into disjoint cyclotomic convolutions. Let $p$ be a prime and consider $p$ point circular convolution. Above we found that

$$
S_{p}=R_{p}^{-1}\left[\begin{array}{ll}
1 &  \tag{3.7}\\
& C_{\Phi_{p}}
\end{array}\right] R_{p}
$$

and therefore

$$
S_{p}^{k}=R_{p}^{-1}\left[\begin{array}{ll}
1 &  \tag{3.8}\\
& C_{\Phi_{p}}^{k}
\end{array}\right] R_{p}
$$

If $\left(A_{p}, B_{p}, C_{p}\right)$ describes a bilinear form for $\Phi_{p}(s)$ convolution, then

$$
S_{p}^{k}=R_{p}^{-1}\left[\begin{array}{ll}
1 &  \tag{3.9}\\
& C_{p}
\end{array}\right] \operatorname{diag}\left(\left[\begin{array}{ll}
1 & \\
& B_{p}
\end{array}\right] R_{p} e_{k}\right)\left[\begin{array}{ll}
1 & \\
& A_{p}
\end{array}\right] R_{p}
$$

and consequently the circular convolution of $h$ and $x$ can be computed by

$$
\begin{equation*}
y=R_{p}^{-1} C\left\{B R_{p} h * A R_{p} x\right\} \tag{3.10}
\end{equation*}
$$

where $A=1 \oplus A_{p}, B=1 \oplus B_{p}$ and $C=1 \oplus C_{p}$. We say $(A, B, C)$ describes a bilinear form for $p$ point circular convolution. Note that if $(D, E, F)$ describes a $(p-1)$ point linear convolution then $A_{p}, B_{p}$ and $C_{p}$ can be taken to be $A_{p}=D, B_{p}=E$ and $C_{p}=G_{p} F$ where $G_{p}$ represents the appropriate reduction operations. Specifically, $G_{p}$ is given by Equation 42 from Preliminaries (2.42).

Next we consider $p^{e}$ point circular convolution. Recall that $S_{p^{e}}=R_{p^{e}}^{-1}\left(\oplus_{i=0}^{e} C_{\Phi_{p^{i}}}\right) R_{p^{e}}$ as in Equation 27 from Preliminaries (2.7) so that the circular convolution is decomposed into a set of $e+1$ disjoint $\Phi_{p^{i}}(s)$ convolutions. If $\left(A_{p^{i}}, B_{p^{i}}, C_{p^{i}}\right)$ describes a bilinear form for $\Phi_{p^{i}}(s)$ convolution and if

$$
\begin{align*}
A & =1 \oplus A_{p} \oplus \cdots \oplus A_{p^{e}} \\
B & =1 \oplus B_{p} \oplus \cdots \oplus B_{p^{e}}  \tag{3.11}\\
C & =1 \oplus C_{p} \oplus \cdots \oplus C_{p^{e}}
\end{align*}
$$

then $\left(A R_{p^{e}}, B R_{p^{e}}, R_{p^{e}}^{-1} C\right)$ describes a bilinear form for $p^{e}$ point circular convolution. In particular, if $\left(D_{d}, E_{d}, F_{d}\right)$ describes a bilinear form for $d$ point linear convolution, then $A_{p^{i}}, B_{p^{i}}$ and $C_{p^{i}}$ can be taken to be

$$
\begin{align*}
A_{p^{i}} & =D_{\phi\left(p^{i}\right)} \\
B_{p^{i}} & =E_{\phi\left(p^{i}\right)}  \tag{3.12}\\
C_{p^{i}} & =G_{p^{i}} F_{\phi\left(p^{i}\right)}
\end{align*}
$$

where $G_{p^{i}}$ represents the appropriate reduction operation and $\phi(\cdot)$ is the Euler totient function. Specifically, $G_{p^{i}}$ has the following form

$$
G_{p^{i}}=\left[\begin{array}{ll}
I_{(p-1) p^{i-1}} & -1_{-\mathrm{p}-1} \otimes I_{p^{i-1}}
\end{array}\left[\begin{array}{c}
I_{(p-2) p^{i-1}-1}  \tag{3.13}\\
0_{p^{i-1}+1,(p-2) p^{i-1}-1}
\end{array}\right]\right]
$$

if $p \geq 3$, while

$$
G_{2^{i}}=\left[I_{2^{i-1}}\left[\begin{array}{c}
-I_{2^{i-1}-1}  \tag{3.14}\\
0_{1,2^{i-1}-1}
\end{array}\right]\right] .
$$

Note that the matrix $R_{p^{e}}$ block diagonalizes $S_{p^{e}}$ and each diagonal block represents a cyclotomic convolution. Correspondingly, the matrices $A, B$ and $C$ of the bilinear form also have a block diagonal structure.

### 3.1.3 The Split Nesting Algorithm

We now describe the split-nesting algorithm for general length circular convolution [22]. Let $n=p_{1}^{e_{1}} \cdots p_{k}^{e_{k}}$ where $p_{i}$ are distinct primes. We have seen that

$$
\begin{equation*}
S_{n}=P^{t} R^{-1}(\underset{d \mid n}{\oplus} \Psi(d)) R P \tag{3.15}
\end{equation*}
$$

where $P$ is the prime factor permutation $P=P_{p_{1}, \cdots, p_{k}}^{e_{k}}$ and $R$ represents the reduction operations. For example, see Equation 46 in Preliminaries (2.46). $R P$ block diagonalizes $S_{n}$ and each diagonal block represents a multi-dimensional cyclotomic convolution. To obtain a bilinear form for a multi-dimensional convolution, we can combine bilinear forms for one-dimensional convolutions. If $\left(A_{p_{j}^{i}}, B_{p_{j}^{i}}, C_{p_{j}^{i}}\right)$ describes a bilinear form for $\Phi_{p_{j}^{i}}(s)$ convolution and if

$$
\begin{align*}
A & =\oplus_{d \mid n} A_{d} \\
B & =\oplus_{d \mid n} B_{d}  \tag{3.16}\\
C & =\oplus_{d \mid n} C_{d}
\end{align*}
$$

with

$$
\begin{align*}
A_{d} & =\otimes_{p \mid d, p \in \mathcal{P}} A_{H_{d}(p)} \\
B_{d} & =\otimes_{p \mid d, p \in \mathcal{P}} B_{H_{d}(p)}  \tag{3.17}\\
C_{d} & =\otimes_{p \mid d, p \in \mathcal{P}} C_{H_{d}(p)}
\end{align*}
$$

where $H_{d}(p)$ is the highest power of $p$ dividing $d$, and $\mathcal{P}$ is the set of primes, then $\left(A R P, B R P, P^{t} R^{-1} C\right)$ describes a bilinear form for $n$ point circular convolution. That is

$$
\begin{equation*}
y=P^{t} R^{-1} C\{B R P h * A R P x\} \tag{3.18}
\end{equation*}
$$

computes the circular convolution of $h$ and $x$.
As above $\left(A_{p_{j}^{i}}, B_{p_{j}^{i}}, C_{p_{j}^{i}}\right)$ can be taken to be $\left(D_{\phi\left(p_{j}^{i}\right)}, E_{\phi\left(p_{j}^{i}\right)}, G_{p_{j}^{i}} F_{\phi\left(p_{j}^{i}\right)}\right)$ where $\left(D_{d}, E_{d}, F_{d}\right)$ describes a bilinear form for $d$ point linear convolution. This is one particular choice for $\left(A_{p_{j}^{i}}, B_{p_{j}^{i}}, C_{p_{j}^{i}}\right)$ - other bilinear forms for cyclotomic convolution that are not derived from linear convolution algorithms exist.

## Example 3.2

A 45 point circular convolution algorithm:

$$
\begin{equation*}
y=P^{t} R^{-1} C\{B R P h * A R P x\} \tag{3.19}
\end{equation*}
$$

where

$$
\begin{array}{ccc}
P & = & P_{9,5} \\
R & = & R_{9,5} \\
A & = & 1 \oplus A_{3} \oplus A_{9} \oplus A_{5} \oplus\left(A_{3} \otimes A_{5}\right) \oplus\left(A_{9} \otimes A_{5}\right)  \tag{3.20}\\
B & = & 1 \oplus B_{3} \oplus B_{9} \oplus B_{5} \oplus\left(B_{3} \otimes B_{5}\right) \oplus\left(B_{9} \otimes B_{5}\right) \\
C & = & 1 \oplus C_{3} \oplus C_{9} \oplus C_{5} \oplus\left(C_{3} \otimes C_{5}\right) \oplus\left(C_{9} \otimes C_{5}\right)
\end{array}
$$

and where $\left(A_{p_{j}^{i}}, B_{p_{j}^{i}}, C_{p_{j}^{i}}\right)$ describes a bilinear form for $\Phi_{p_{j}^{i}}(s)$ convolution.

### 3.1.4 The Matrix Exchange Property

The matrix exchange property is a useful technique that, under certain circumstances, allows one to save computation in carrying out the action of bilinear forms [11]. Suppose

$$
\begin{equation*}
y=C\{A x * B h\} \tag{3.21}
\end{equation*}
$$

as in (3.18). When $h$ is known and fixed, $B h$ can be pre-computed so that $y$ can be found using only the operations represented by $C$ and $A$ and the point by point multiplications denoted by $*$. The operation of $B$ is absorbed into the multiplicative constants. Note that in (3.18), the matrix corresponding to $C$ is more complicated than is $B$. It is therefore advantageous to absorb the work of $C$ instead of $B$ into the multiplicative constants if possible. This can be done when $y$ is the circular convolution of $x$ and $h$ by using the matrix exchange property.

To explain the matrix exchange property we draw from [11]. Note that $y=C \operatorname{diag}(A x) B h$, so that Cdiag $(A x) B$ must be the corresponding circulant matrix,

$$
\operatorname{Cdiag}(A x) B=\left[\begin{array}{cccc}
x_{0} & x_{n-1} & \cdots & x_{1}  \tag{3.22}\\
x_{1} & x_{0} & & x_{2} \\
\vdots & & & \\
x_{n-1} & x_{n-2} & & x_{0}
\end{array}\right]
$$

Since $\operatorname{Cdiag}(A x) B=J(\operatorname{Cdiag}(A x) B)^{t} J$ where $J$ is the reversal matrix, one gets

$$
\begin{array}{rlc}
y & = & C\{A x * B h\} \\
& = & \operatorname{Cdiag}(A x) B h \\
& = & J(\operatorname{Cdiag}(A x) B)^{t} J h  \tag{3.23}\\
& = & J B^{t} \operatorname{diag}(A x) C^{t} J h \\
& = & J B^{t}\left\{A x * C^{t} J h\right\}
\end{array}
$$

As noted in [11], the matrix exchange property can be used whenever $y=T(x) h$ where $T(x)$ satisfies $T(x)=J_{1} T(x)^{t} J_{2}$ for some matrices $J_{1}$ and $J_{2}$. In that case one gets $y=J_{1} B^{t}\left\{A x * C^{t} J_{2} h\right\}$.

Applying the matrix exchange property to (3.18) one gets

$$
\begin{equation*}
y=J P^{t} R^{t} B^{t}\left\{C^{t} R^{-t} P J h * A R P x\right\} \tag{3.24}
\end{equation*}
$$

## Example 3.3

A 45 point circular convolution algorithm:

$$
\begin{equation*}
y=J P^{t} R^{t} B^{t}\{u * A R P x\} \tag{3.25}
\end{equation*}
$$

where $u=C^{t} R^{-t} P J h$ and

$$
\begin{array}{rcc}
P & = & P_{9,5} \\
R & = & R_{9,5} \\
A & = & 1 \oplus A_{3} \oplus A_{9} \oplus A_{5} \oplus\left(A_{3} \otimes A_{5}\right) \oplus\left(A_{9} \otimes A_{5}\right)  \tag{3.26}\\
B^{t} & = & 1 \oplus B_{3}^{t} \oplus B_{9}^{t} \oplus B_{5}^{t} \oplus\left(B_{3}^{t} \otimes B_{5}^{t}\right) \oplus\left(B_{9}^{t} \otimes B_{5}^{t}\right) \\
C^{t} & = & 1 \oplus C_{3}^{t} \oplus C_{9}^{t} \oplus C_{5}^{t} \oplus\left(C_{3}^{t} \otimes C_{5}^{t}\right) \oplus\left(C_{9}^{t} \otimes C_{5}^{t}\right)
\end{array}
$$

and where $\left(A_{p_{j}^{i}}, B_{p_{j}^{i}}, C_{p_{j}^{i}}\right)$ describes a bilinear form for $\Phi_{p_{j}^{i}}(s)$ convolution.

## Chapter 4

## A Bilinear Form for the DFT ${ }^{\text { }}$

### 4.1 A Bilinear Form for the DFT

A bilinear form for a prime length DFT can be obtained by making minor changes to a bilinear form for circular convolution. This relies on Rader's observation that a prime $p$ point DFT can be computed by computing a $p-1$ point circular convolution and by performing some extra additions [25]. It turns out that when the Winograd or the split nesting convolution algorithm is used, only two extra additions are required. After briefly reviewing Rader's conversion of a prime length DFT in to a circular convolution, we will discuss a bilinear form for the DFT.

### 4.1.1 Rader's Permutation

To explain Rader's conversion of a prime $p$ point DFT into a $p-1$ point circular convolution [5] we recall the definition of the DFT

$$
\begin{equation*}
y(k)=\sum_{n=0}^{p-1} x(n) W^{k n} \tag{4.1}
\end{equation*}
$$

with $W=\exp -j 2 \pi / p$. Also recall that a primitive root of $p$ is an integer $r$ such that $<r^{m}>_{p}$ maps the integers $m=0, \cdots, p-2$ to the integers $1, \cdots, p-1$. Letting $n=r^{-m}$ and $k=r^{l}$, where $r^{-m}$ is the inverse of $r^{m}$ modulo $p$, the DFT becomes

$$
\begin{equation*}
y\left(r^{l}\right)=x(0)+\sum_{m=0}^{p-2} x\left(r^{-m}\right) W^{r^{l} r^{-m}} \tag{4.2}
\end{equation*}
$$

for $l=0, \cdots, p-2$. The ' DC ' term fis given by $y(0)=\sum_{n=0}^{p-1} x(n)$. By defining new functions

$$
\begin{equation*}
x^{\prime}(m)=x\left(r^{-m}\right), \quad y^{\prime}(m)=y\left(r^{m}\right), \quad W^{\prime}(m)=W^{r^{m}} \tag{4.3}
\end{equation*}
$$

which are simply permuted versions of the original sequences, the DFT becomes

$$
\begin{equation*}
y^{\prime}(l)=x(0)+\sum_{m=0}^{p-2} x^{\prime}(m) W^{\prime}(l-m) \tag{4.4}
\end{equation*}
$$

for $l=0, \cdots, p-2$. This equation describes circular convolution and therefore any circular convolution algorithm can be used to compute a prime length DFT. It is only necessary to (i) permute the input, the roots of unity and the output, (ii) add $x(0)$ to each term in (4.4) and (iii) compute the DC term.

[^4]To describe a bilinear form for the DFT we first define a permutation matrix $Q$ for the permutation above. If $p$ is a prime and $r$ is a primitive root of $p$, then let $Q_{r}$ be the permutation matrix defined by

$$
\begin{equation*}
Q e_{<r^{k}>_{p}-1}=e_{k} \tag{4.5}
\end{equation*}
$$

for $0 \leq k \leq p-2$ where $e_{k}$ is the $k^{t h}$ standard basis vector. Let the $\tilde{w}$ be a $p-1$ point vector of the roots of unity:

$$
\begin{equation*}
\tilde{w}=\left(W^{1}, \cdots, W^{p-1}\right)^{t} \tag{4.6}
\end{equation*}
$$

If $s$ is the inverse of $r$ modulo $p$ (that is, $r s=1$ modulo $p$ ) and $\tilde{x}=(x(1), \cdots, x(p-1))^{t}$, then the circular convolution of (4.4) can be computed with the bilinear form of :

$$
\begin{equation*}
Q_{s}^{t} J P^{t} R^{t} B^{t}\left\{C^{t} R^{-t} P J Q_{s} \tilde{w} * A R P Q_{r} \tilde{x}\right\} \tag{4.7}
\end{equation*}
$$

This bilinear form does not compute $y(0)$, the DC term. Furthermore, it is still necessary to add the $x(0)$ term to each of the elements of (4.7) to obtain $y(1), \cdots, y(p-1)$.

### 4.1.2 Calculation of the DC term

The computation of $y(0)$ turns out to be very simple when the bilinear form (4.7) is used to compute the circular convolution in (4.4). The first element of $A R P Q_{r} \tilde{x}$ in (4.7) is the residue modulo the polynomial $s-1$, that is, the first element of this vector is the sum of the elements of $\tilde{x}$. (The first row of the matrix, $R$, representing the reduction operation is a row of 1 's, and the matrices $P$ and $Q_{r}$ are permutation matrices.) Therefore, the DC term can be computed by adding the first element of $A R P Q_{r} \tilde{x}$ to $x(0)$. Hence, when the Winograd or split nesting algorithm is used to perform the circular convolution of (4.7), the computation of the DC term requires only one extra complex addition for complex data.

The addition $x(0)$ to each of the elements of (4.7) also requires only one complex addition. By adding $x$ (0) to the first element of $\left\{C^{t} R^{-t} P J Q_{s} \tilde{w} * A R P Q_{r} \tilde{x}\right\}$ in (4.7) and applying $Q_{s}^{t} J P^{t} R^{t}$ to the result, $x$ (0) is added to each element. (Again, this is because the first column of $R^{t}$ is a column of 1 's, and the matrices $Q_{s}^{t}, J$ and $P^{t}$ are permutation matrices.)

Although the DFT can be computed by making these two extra additions, this organization of additions does not yield a bilinear form. However, by making a minor modification, a bilinear form can be retrieved. The method described above can be illustrated in Figure 4.1 with $u=C^{t} R^{-t} P J Q_{s} \tilde{w}$.

Figure 4.1: The flow graph for the computation of the DFT.

Clearly, the structure highlighted in the dashed box can be replaced by the structure in Figure 4.2.

Figure 4.2: The flow graph for the bilinear form.

By substituting the second structure for the first, a bilinear form is obtained. The resulting bilinear form for a prime length DFT is

$$
y=\left[\begin{array}{cc}
1 &  \tag{4.8}\\
& Q_{s}^{t} J P^{t} R^{t} B^{t}
\end{array}\right] U_{p}^{t}\left\{V_{p}\left[\begin{array}{cc}
1 & \\
& C^{t} R^{-t} P J Q_{s}
\end{array}\right] w * U_{p}\left[\begin{array}{ll}
1 & \\
& A R P Q_{r}
\end{array}\right] x\right\}
$$

where $w=\left(W^{0}, \cdots, W^{p-1}\right)^{t}, x=(x(0), \cdots, x(p-1))^{t}$, and where $U_{p}$ is the matrix with the form

$$
U_{p}=\left[\begin{array}{lllll}
1 & 1 & & &  \tag{4.9}\\
& 1 & & & \\
& & 1 & & \\
& & & \ddots & \\
& & & & 1
\end{array}\right]
$$

and $V_{p}$ is the matrix with the form

$$
U_{p}=\left[\begin{array}{ccccc}
1 & & & &  \tag{4.10}\\
-1 & 1 & & & \\
& & 1 & & \\
& & & \ddots & \\
& & & & 1
\end{array}\right]
$$

## Chapter 5

## Implementing Kronecker Products Efficiently'

### 5.1 Implementing Kronecker Products Efficiently

In the algorithm described above we encountered expressions of the form $A_{1} \otimes A_{2} \otimes \cdots \otimes A_{n}$ which we denote by $\otimes_{i=1}^{n} A_{i}$. To calculate the product $\left(\otimes_{i} A_{i}\right) x$ it is computationally advantageous to factor $\otimes_{i} A_{i}$ into terms of the form $I \otimes A_{i} \otimes I[2]$. Then each term represents a set of copies of $A_{i}$. First, recall the following property of Kronecker products

$$
\begin{equation*}
A B \otimes C D=(A \otimes C)(B \otimes D) \tag{5.1}
\end{equation*}
$$

This property can be used to factor $\otimes_{i} A_{i}$ in the following way. Let the number of rows and columns of $A_{i}$ be denoted by $r_{i}$ and $c_{i}$ respectively. Then

$$
\begin{array}{rlc}
A_{1} \otimes A_{2} & = & A_{1} I_{c_{1}} \otimes I_{r_{2}} A_{2} \\
& =\left(A_{1} \otimes I_{r_{2}}\right)\left(I_{c_{1}} \otimes A_{2}\right) \tag{5.2}
\end{array}
$$

But we can also write

$$
\begin{align*}
A_{1} \otimes A_{2} & =\quad I_{r_{1}} A_{1} \otimes A_{2} I_{c_{2}}  \tag{5.3}\\
& =\left(I_{r_{1}} \otimes A_{2}\right)\left(A_{1} \otimes I_{c_{2}}\right)
\end{align*}
$$

Note that in factorization (5.2), copies of $A_{2}$ are applied to the data vector $x$ first, followed by copies of $A_{1}$. On the other hand, in factorization (5.3), copies of $A_{1}$ are applied to the data vector $x$ first, followed by copies of $A_{2}$. These two factorizations can be distinguished by the sequence in which $A_{1}$ and $A_{2}$ are ordered.

Lets compare the computational complexity of factorizations (5.2) and (5.3). Notice that (5.2) consists of $r_{2}$ copies of $A_{1}$ and $c_{1}$ copies of $A_{2}$, therefore (5.2) has a computational cost of $r_{2} \mathcal{Q}_{1}+c_{1} \mathcal{Q}_{2}$ where $\mathcal{Q}_{i}$ is the computational cost of $A_{i}$. On the other hand, the computational cost of (5.3) is $c_{2} \mathcal{Q}_{1}+r_{1} \mathcal{Q}_{2}$. That is, the factorizations (5.2) and (5.3) have in general different computational costs when $A_{i}$ are not square. Further, observe that (5.2) is the more efficient factorization exactly when

$$
\begin{equation*}
r_{2} \mathcal{Q}_{1}+c_{1} \mathcal{Q}_{2}<c_{2} \mathcal{Q}_{1}+r_{1} \mathcal{Q}_{2} \tag{5.4}
\end{equation*}
$$

or equivalently, when

$$
\begin{equation*}
\frac{r_{1}-c_{1}}{\mathcal{Q}_{1}}>\frac{r_{2}-c_{2}}{\mathcal{Q}_{2}} \tag{5.5}
\end{equation*}
$$

[^5]Consequently, in the more efficient factorization, the operation $A_{i}$ applied to the data vector $x$ first is the one for which the ratio $\left(r_{i}-c_{i}\right) / \mathcal{Q}_{i}$ is the more negative. If $r_{1}>c_{1}$ and $r_{2}<c_{2}$ then (5.4) is always true ( $\mathcal{Q}_{i}$ is always positive). Therefore, in the most computationally efficient factorization of $A_{1} \otimes A_{2}$, matrices with fewer rows than columns are always applied to the data vector $x$ before matrices with more rows than columns. If both matrices are square, then their ordering does not affect the computational efficiency, because in that case each ordering has the same computation cost.

We now consider the Kronecker product of more than two matrices. For the Kronecker product $\otimes_{i=1}^{n} A_{i}$ there are $n$ ! possible different ways in which to order the operations $A_{i}$. For example

$$
\begin{align*}
A_{1} \otimes A_{2} \otimes A_{3} & =\left(A_{1} \otimes I_{r_{2} r_{3}}\right)\left(I_{c_{1}} \otimes A_{2} \otimes I_{r_{3}}\right)\left(I_{c_{1} c_{2}} \otimes A_{3}\right) \\
& =\left(A_{1} \otimes I_{r_{2} r_{3}}\right)\left(I_{c_{1} r_{2}} \otimes A_{3}\right)\left(I_{c_{1}} \otimes A_{2} \otimes I_{c_{3}}\right) \\
& =\left(I_{r_{1}} \otimes A_{2} \otimes I_{r_{3}}\right)\left(A_{1} \otimes I_{c_{2} r_{3}}\right)\left(I_{c_{1} c_{2}} \otimes A_{3}\right)  \tag{5.6}\\
& =\left(I_{r_{1}} \otimes A_{2} \otimes I_{r_{3}}\right)\left(I_{r_{1} c_{2}} \otimes A_{3}\right)\left(A_{1} \otimes I_{c_{2} c_{3}}\right) \\
& =\left(I_{r_{1} r_{2}} \otimes A_{3}\right)\left(A_{1} \otimes I_{r_{2} c_{3}}\right)\left(I_{c_{1}} \otimes A_{2} \otimes I_{c_{3}}\right) \\
& =\left(I_{r_{1} r_{2}} \otimes A_{3}\right)\left(I_{r_{1}} \otimes A_{2} \otimes I_{c_{3}}\right)\left(A_{1} \otimes I_{c_{2} c_{3}}\right)
\end{align*}
$$

Each factorization of $\otimes_{i} A_{i}$ can be described by a permutation $g(\cdot)$ of $\{1, \ldots, n\}$ which gives the order in which $A_{i}$ is applied to the data vector $x . A_{g(1)}$ is the first operation applied to the data vector $x, A_{g(2)}$ is the second, and so on. For example, the factorization (5.6) is described by the permutation $g(1)=3, g(2)=1$, $g(3)=2$. For $n=3$, the computational cost of each factorization can be written as

$$
\begin{equation*}
\mathcal{C}(g)=\mathcal{Q}_{g(1)} c_{g(2)} c_{g(3)}+r_{g(1)} \mathcal{Q}_{g(2)} c_{g(3)}+r_{g(1)} r_{g(2)} \mathcal{Q}_{g(3)} \tag{5.7}
\end{equation*}
$$

In general

$$
\begin{equation*}
\mathcal{C}(g)=\sum_{i=1}^{n}\left(\prod_{j=1}^{i-1} r_{g(j)}\right) \mathcal{Q}_{g(i)}\left(\prod_{j=i+1}^{n} c_{g(j)}\right) \tag{5.8}
\end{equation*}
$$

Therefore, the most efficient factorization of $\otimes_{i} A_{i}$ is described by the permutation $g(\cdot)$ that minimizes $\mathcal{C}$.
It turns out that for the Kronecker product of more than two matrices, the ordering of operations that describes the most efficient factorization of $\otimes_{i} A_{i}$ also depends only on the ratios $\left(r_{i}-c_{i}\right) / \mathcal{Q}_{i}$. To show that this is the case, suppose $u(\cdot)$ is the permutation that minimizes $\mathcal{C}$, then $u(\cdot)$ has the property that

$$
\begin{equation*}
\frac{r_{u(k)}-c_{u(k)}}{\mathcal{Q}_{u(k)}} \leq \frac{r_{u(k+1)}-c_{u(k+1)}}{\mathcal{Q}_{u(k+1)}} \tag{5.9}
\end{equation*}
$$

for $k=1, \cdots, n-1$. To support this, note that since $u(\cdot)$ is the permutation that minimizes $\mathcal{C}$, we have in particular

$$
\begin{equation*}
\mathcal{C}(u) \leq \mathcal{C}(v) \tag{5.10}
\end{equation*}
$$

where $v(\cdot)$ is the permutation defined by the following:

$$
v(i)=\left\{\begin{array}{cc}
u(i) & i<k, i>k+1 \\
u(k+1) & i=k  \tag{5.11}\\
u(k) & i=k+1
\end{array} .\right.
$$

Because only two terms in (5.8) are different, we have from (5.10)

$$
\begin{equation*}
\sum_{i=k}^{k+1}\left(\prod_{j=1}^{i-1} r_{u(j)}\right) \mathcal{Q}_{u(i)}\left(\prod_{j=i+1}^{n} c_{u(j)}\right) \leq \sum_{i=k}^{k+1}\left(\prod_{j=1}^{i-1} r_{v(j)}\right) \mathcal{Q}_{v(i)}\left(\prod_{j=i+1}^{n} c_{v(j)}\right) \tag{5.12}
\end{equation*}
$$

which, after canceling common terms from each side, gives

$$
\begin{equation*}
\mathcal{Q}_{u(k)} c_{u(k+1)}+r_{u(k)} \mathcal{Q}_{u(k+1)} \leq \mathcal{Q}_{v(k)} c_{v(k+1)}+r_{v(k)} \mathcal{Q}_{v(k+1)} \tag{5.13}
\end{equation*}
$$

Since $v(k)=u(k+1)$ and $v(k+1)=u(k)$ this becomes

$$
\begin{equation*}
\mathcal{Q}_{u(k)} c_{u(k+1)}+r_{u(k)} \mathcal{Q}_{u(k+1)} \leq \mathcal{Q}_{u(k+1)} c_{u(k)}+r_{u(k+1)} \mathcal{Q}_{u(k)} \tag{5.14}
\end{equation*}
$$

which is equivalent to (5.9). Therefore, to find the best factorization of $\otimes_{i} A_{i}$ it is necessary only to compute the ratios $\left(r_{i}-c_{i}\right) / \mathcal{Q}_{i}$ and to order them in an non-decreasing order. The operation $A_{i}$ whose index appears first in this list is applied to the data vector $x$ first, and so on

As above, if $r_{u(k+1)}>c_{u(k+1)}$ and $r_{u(k)}<c_{u(k)}$ then (5.14) is always true. Therefore, in the most computationally efficient factorization of $\otimes_{i} A_{i}$, all matrices with fewer rows than columns are always applied to the data vector $x$ before any matrices with more rows than columns. If some matrices are square, then their ordering does not affect the computational efficiency as long as they are applied after all matrices with fewer rows than columns and before all matrices with more rows than columns.

Once the permutation $g(\cdot)$ that minimizes $\mathcal{C}$ is determined by ordering the ratios $\left(r_{i}-c_{i}\right) / \mathcal{Q}_{i}, \otimes_{i} A_{i}$ can be written as
where

$$
\begin{gather*}
a(i)=\prod_{k=1}^{g(i)-1} \gamma(i, k)  \tag{5.16}\\
b(i)=\prod_{k=g(i)+1}^{n} \gamma(i, k) \tag{5.17}
\end{gather*}
$$

and where $\gamma(\cdot)$ is defined by

$$
\gamma(i, k)=\left\{\begin{array}{ll}
r_{k} & \text { if } g(i)>g(k)  \tag{5.18}\\
c_{k} & \text { if } g(i)<g(k)
\end{array} .\right.
$$

### 5.1.1 Some Matlab Code

A Matlab program that computes the permutation that describes the computationally most efficient factorization of $\otimes_{i=1}^{n} A_{i}$ is $\operatorname{cgc}()$. It also gives the resulting computational cost. It requires the computational cost of each of the matrices $A_{i}$ and the number of rows and columns of each.

```
    function [g,C] = cgc(Q,r,c,n)
% [g,C] = cgc(Q,r,c,n);
% Compute g and C
% g : permutation that minimizes C
% C : computational cost of Kronecker product of A(1),...,A(n)
% Q : computation cost of A(i)
% r : rows of A(i)
% c : columns of A(i)
% n : number of terms
f = find(Q==0);
Q(f) = eps * ones(size(Q(f)));
```

```
Q = Q(:);
r = r(:);
c = c(:);
[s,g] = sort((r-c)./Q);
C = 0;
for i = 1:n
    C = C + prod}(r(g(1:i-1)))*Q(g(i))*\operatorname{prod}(\textrm{c}(\textrm{g}(\textrm{i}+1:\textrm{n})))
end
C = round(C);
```

The Matlab program kpi() implements the Kronecker product $\otimes_{i=1}^{n} A_{i}$.

```
    function y = kpi(d,g,r,c,n,x)
% y = kpi(d,g,r,c,n,x);
% Kronecker Product : A(d(1)) kron ... kron A(d(n))
% g : permutation of 1,...,n
% r : [r(1),...,r(n)]
% c : [c(1),..,c(n)]
%r(i) : rows of A(d(i))
% c(i) : columns of A(d(i))
% n : number of terms
for i = 1:n
    a = 1;
    for k = 1:(g(i)-1)
        if i > find(g==k)
            a = a * r(k);
        else
            a = a * c(k);
        end
    end
    b = 1;
    for k = (g(i)+1):n
        if i > find(g==k)
                b}=\textrm{b}*\textrm{r}(\textrm{k})
        else
                b}=\textrm{b}*\textrm{c}(\textrm{k})
        end
    end
    % y = (I(a) kron A(d(g(i))) kron I(b)) * x;
    y = IAI(d(g(i)),a,b,x);
end
```

where the last line of code calls a function that implements $\left(I_{a} \otimes A_{d(g(i))} \otimes I_{b}\right) x$. That is, the program IAI ( $\mathrm{i}, \mathrm{a}, \mathrm{b}, \mathrm{x}$ ) implements $\left(I_{a} \otimes A(i) \otimes I_{b}\right) x$.

The Matlab program IAI implements $y=\left(I_{m} \otimes A \otimes I_{n}\right) x$

```
function y = IAI(A,r,c,m,n,x)
```

$\% \mathrm{y}=(\mathrm{I}(\mathrm{m})$ kron $A$ kron $\mathrm{I}(\mathrm{n}) \mathrm{x}$
$\% r$ : number of rows of $A$
$\%$ c : number of columns of $A$
$\mathrm{v}=0: \mathrm{n}: \mathrm{n} *(\mathrm{r}-1)$;
$\mathrm{u}=0: \mathrm{n}: \mathrm{n} *(\mathrm{c}-1)$;
for $i=0: m-1$

```
    for j = 0:n-1
        y(v+i*r*n+j+1) = A * x (u+i*c*n+j+1);
    end
end
```

It simply uses two loops to implement the $m n$ copies of $A$. Each copy of $A$ is applied to a different subset of the elements of $x$.

### 5.1.2 Vector/Parallel Interpretation

The command $I \otimes A \otimes I$ where $\otimes$ is the Kronecker (or Tensor) product can be interpreted as a vector/parallel command [7], [36]. In these references, the implementation of these commands is discussed in detail and they have found that the Tensor product is "an extremely useful tool for matching algorithms to computer architectures [7]."

The expression $I \otimes A$ can easily be seen to represent a parallel command:

$$
I \otimes A=\left[\begin{array}{llll}
A & & &  \tag{5.19}\\
& A & & \\
& & \ddots & \\
& & & A
\end{array}\right]
$$

Each block along the diagonal acts on non-overlapping sections of the data vector - so that each section can be performed in parallel. Since each section represents exactly the same operation, this form is amenable to implementation on a computer with a parallel architectural configuration. The expression $A \otimes I$ can be similarly seen to represent a vector command, see [7].

It should also be noted that by employing 'stride' permutations, the command $(I \otimes A \otimes I) x$ can be replaced by either $(I \otimes A) x$ or $(A \otimes I) x[7]$, [36]. It is only necessary to permute the input and output. It is also the case that these stride permutations are natural loading and storing commands for some architectures.

In the programs we have written in conjunction with this paper we implement the commands $y=$ $(I \otimes A \otimes I) x$ with loops in a set of subroutines. The circular convolution and prime length FFT programs we present, however, explicitly use the form $I \otimes A \otimes I$ to make clear the structure of the algorithm, to make them more modular and simpler, and to make them amenable to implementation on special architectures. In fact, in [7] it is suggested that it might be practical to develop tensor product compilers. The FFT programs we have generated will be well suited for such compilers.

## Chapter 6

## Programs for Circular Convolution

### 6.1 Programs for Circular Convolution

To write a program that computes the circular convolution of $h$ and $x$ using the bilinear form Equation 24 in Bilinear Forms for Circular Convolution (3.24) we need subprograms that carry out the action of $P, P^{t}, R$, $R^{t}, A$ and $B^{t}$. We are assuming, as is usually done, that $h$ is fixed and known so that $u=C^{t} R^{-t} P J h$ can be pre-computed and stored. To compute these multiplicative constants $u$ we need additional subprograms to carry out the action of $C^{t}$ and $R^{-t}$ but the efficiency with which we compute $u$ is unimportant since this is done beforehand and $u$ is stored.

In Prime Factor Permutations (Section 2.2: Prime Factor Permutations) we discussed the permutation $P$ and a program for it pfp() appears in the appendix. The reduction operations $R, R^{t}$ and $R^{-t}$ we have described in Reduction Operations (Section 2.3: Reduction Operations) and programs for these reduction operations KRED () etc, also appear in the appendix. To carry out the operation of $A$ and $B^{t}$ we need to be able to carry out the action of $A_{d_{1}} \otimes \cdots \otimes A_{d_{k}}$ and this was discussed in Implementing Kronecker Products Efficiently (Chapter 5). Note that since $A$ and $B^{t}$ are block diagonal, each diagonal block can be done separately. However, since they are rectangular, it is necessary to be careful so that the correct indexing is used.

To facilitate the discussion of the programs we generate, it is useful to consider an example. Take as an example the 45 point circular convolution algorithm listed in the appendix. From Equation 19 from Bilinear Forms for Circular Convolution (3.19) we find that we need to compute $x=P_{9,5} x$ and $x=R_{9,5} x$. These are the first two commands in the program.

We noted above that bilinear forms for linear convolution, $\left(D_{d}, E_{d}, F_{d}\right)$, can be used for these cyclotomic convolutions. Specifically we can take $A_{p^{i}}=D_{\phi\left(p^{i}\right)}, B_{p^{i}}=E_{\phi\left(p^{i}\right)}$ and $C_{p^{i}}=G_{p^{i}} F_{\phi\left(p^{i}\right)}$. In this case Equation 20 in Bilinear Forms for Circular Convolution (3.20) becomes

$$
\begin{equation*}
A=1 \oplus D_{2} \oplus D_{6} \oplus D_{4} \oplus\left(D_{2} \otimes D_{4}\right) \oplus\left(D_{6} \otimes D_{4}\right) \tag{6.1}
\end{equation*}
$$

In our approach this is what we have done. When we use the bilinear forms for convolution given in the appendix, for which $D_{4}=D_{2} \otimes D_{2}$ and $D_{6}=D_{2} \otimes D_{3}$, we get

$$
\begin{equation*}
A=1 \oplus D_{2} \oplus\left(D_{2} \otimes D_{3}\right) \oplus\left(D_{2} \otimes D_{2}\right) \oplus\left(D_{2} \otimes D_{2} \otimes D_{2}\right) \oplus\left(D_{2} \otimes D_{3} \otimes D_{2} \otimes D_{2}\right) \tag{6.2}
\end{equation*}
$$

and since $E_{d}=D_{d}$ for the linear convolution algorithms listed in the appendix, we get

$$
\begin{equation*}
B=1 \oplus D_{2}^{t} \oplus\left(D_{2}^{t} \otimes D_{3}^{t}\right) \oplus\left(D_{2}^{t} \otimes D_{2}^{t}\right) \oplus\left(D_{2}^{t} \otimes D_{2}^{t} \otimes D_{2}^{t}\right) \oplus\left(D_{2}^{t} \otimes D_{3}^{t} \otimes D_{2}^{t} \otimes D_{2}^{t}\right) \tag{6.3}
\end{equation*}
$$

From the discussion above, we found that the Kronecker products like $D_{2} \otimes D_{2} \otimes D_{2}$ appearing in these expressions are best carried out by factoring the product in to factors of the form $I_{a} \otimes D_{2} \otimes I_{b}$. Therefore we need

[^6]a program to carry out $\left(I_{a} \otimes D_{2} \otimes I_{b}\right) x$ and $\left(I_{a} \otimes D_{3} \otimes I_{b}\right) x$. These function are called ID2I ( $\mathrm{a}, \mathrm{b}, \mathrm{x}$ ) and ID3I ( $\mathrm{a}, \mathrm{b}, \mathrm{x}$ ) and are listed in the appendix. The transposed form, $\left(I_{a} \otimes D_{2}^{t} \otimes I_{b}\right) x$, is called ID2tI ( $\mathrm{a}, \mathrm{b}, \mathrm{x}$ )

To compute the multiplicative constants we need $C^{t}$. Using $C_{p^{i}}=G_{p^{i}} F_{\phi\left(p^{i}\right)}$ we get

$$
\begin{array}{rlr}
C^{t} & = & 1 \oplus F_{2}^{t} G_{3}^{t} \oplus F_{6}^{t} G_{9}^{t} \oplus F_{4}^{t} G_{5}^{t} \oplus\left(F_{2}^{t} G_{3}^{t} \otimes F_{4}^{t} G_{5}^{t}\right) \oplus\left(F_{6}^{t} G_{9}^{t} \otimes F_{4}^{t} G_{5}^{t}\right)  \tag{6.4}\\
& = & 1 \oplus F_{2}^{t} G_{3}^{t} \oplus F_{6}^{t} G_{9}^{t} \oplus F_{4}^{t} G_{5}^{t} \oplus\left(F_{2}^{t} \otimes F_{4}^{t}\right)\left(G_{3}^{t} \otimes G_{5}^{t}\right) \oplus\left(F_{6}^{t} \otimes F_{4}^{t}\right)\left(G_{9}^{t} \otimes G_{5}^{t}\right)
\end{array}
$$

The Matlab function KFt carries out the operation $F_{d_{1}} \otimes \cdots F_{d_{K}}$. The Matlab function Kcrot implements the operation $G_{p_{1}^{e_{1}}} \otimes \cdots G_{p_{K}^{e_{K}}}$. They are both listed in the appendix.

### 6.1.1 Common Functions

By recognizing that the convolution algorithms for different lengths share a lot of the same computations, it is possible to write a set of programs that take advantage of this. The programs we have generated call functions from a relatives small set. Each program calls these functions with different arguments, in differing orders, and a different number of times. By organizing the program structure in a modular way, we are able to generate relatively compact code for a wide variety of lengths.

In the appendix we have listed code for the following functions, from which we create circular convolution algorithms. In the next section we generate FFT programs using this same set of functions.

Prime Factor Permutations: The Matlab function pfp implements this permutation of Prime Factor Permutations (Section 2.2: Prime Factor Permutations). Its transpose is implemented by pfpt .
Reduction Operations: The Matlab function KRED implements the reduction operations of Reduction Operations (Section 2.3: Reduction Operations). Its transpose is implemented by tKRED . Its inverse transpose is implemented by itKRED and this function is used only for computing the multiplicative constants.
Linear Convolution Operations: ID2I and ID3I are Matlab functions for the operations $I \otimes D_{2} \otimes I$ and $I \otimes D_{3} \otimes I$. These linear convolution operations are also described in the appendix 'Bilinear Forms for Linear Convolution.' ID2tI and ID3tI implement the transposes, $I \otimes D_{2}^{t} \otimes I$ and $I \otimes D_{3}^{t} \otimes I$.

### 6.1.2 Operation Counts

Table 6.1 lists operation counts for some of the circular convolution algorithms we have generated. The operation counts do not include any arithmetic operations involved in the index variable or loops. They include only the arithmetic operations that involve the data sequence $x$ in the convolution of $x$ and $h$.

The table in [23] for the split nesting algorithm gives very similar arithmetic operation counts. For all lengths not divisible by 9 , the algorithms we have developed use the same number of multiplications and the same number or fewer additions. For lengths which are divisible by 9 , the algorithms described in [23] require fewer additions than do ours. This is because the algorithms whose operation counts are tabulated in the table in [23] use a special $\Phi_{9}(s)$ convolution algorithm. It should be noted, however, that the efficient $\Phi_{9}(s)$ convolution algorithm of [23] is not constructed from smaller algorithms using the Kronecker product, as is ours. As we have discussed above, the use of the Kronecker product facilitates adaptation to special computer architectures and yields a very compact program with function calls to a small set of functions.

| N | muls | adds |  | N | muls | adds | N | muls | adds | N | muls | adds |

| 20 | 50 | 214 | 70 | 320 | 1554 | 210 | 1280 | 6182 | 720 | 7790 | 30374 |  |
| 21 | 64 | 317 | 72 | 266 | 1250 | 216 | 1316 | 6328 | 756 | 7520 | 38144 |  |

Table 6.1: Operation counts for split nesting circular convolution algorithms
It is possible to make further improvements to the operation counts given in Table 6.1[19], [23]. Specifically, algorithms for prime power cyclotomic convolution based on the polynomial transform, although more complicated, will give improvements for the longer lengths listed [19], [23]. These improvements can be easily included in the code generating program we have developed.

## Chapter 7

# Programs for Prime Length FFTs' 

### 7.1 Programs for Prime Length FFTs

Using the circular convolution algorithms described above, we can easily design algorithms for prime length FFTs. The only modifications that needs to be made involve the permutation of Rader [26] and the correct calculation of the DC term $(y(0))$. These modifications are easily made to the above described approach. It simply requires a few extra commands in the programs. Note that the multiplicative constants are computed directly, since we have programs for all the relevant operations.

In the version we have currently implemented and verified for correctness, we precompute the multiplicative constants, the input permutation and the output permutation. From Equation 8 from A Bilinear Form for the DFT (4.8), the multiplicative constants are given by $V_{p}\left(1 \oplus C^{t} R^{-t} P J Q_{s}\right) w$, the input permutation is given by $1 \oplus P Q_{r}$, and the output permutation is given by $1 \oplus Q_{s}^{t} J P^{t}$. The multiplicative constants, the input and output permutation are each stored as vectors. These vectors are then passed to the prime length FFT program, which consists of the appropriate function calls, see the appendix. In previous prime length FFT modules, the input and output permutations can be completely absorbed in to the computational instructions. This is possible because they are written as straight line code. It is simple to modify the code generating program we have implemented so that it produces straight line code and absorbs the permutations in to the computational program instructions.

In an in-place in-order prime factor algorithm for the DFT [6], [33], the necessary permuted forms of the DFT can be obtained by modifying the multiplicative constants. This can be easily done by permuting the roots of unity, $w$, in the expression for the multiplicative constants [6], [12], nothing else in the structure of the algorithm needs to be changed. By changing the multiplicative constants, it is not possible, however, to omit the permutation required for Rader's conversion of the prime length DFT in to circular convolution.

### 7.1.1 Operation Counts

Table 7.1 lists the arithmetic operations incurred by the FFT programs we have generated and verified for correctness. Note that the number of additions and multiplications incurred by the programs we have generated are the same as previously existing programs for prime lengths up to and including 13 . For $p=17$ a program with 70 multiplications and 314 additions has been written, and for $p=19$ a program with 76 multiplications and 372 additions has been written [14]. Thus for the length $p=17$, the program we have generated requires fewer total arithmetic operations, while for $p=19$, ours uses more.

There are several table of operation counts in [16], each table corresponding to a different variation of the algorithms used in that paper. For each variation, the algorithms we have described use fewer additions and fewer multiplications. The focus of [16], however, is the implementation of prime point FFT on various computer architectures and the advantage that can be gained from matching algorithms with architectures.

[^7]It should be noted that the highest prime in [16] for which an FFT was designed is 29. Although we have not executed the programs described in this paper on these computers, they are, as mentioned above, written to be easily adapted to parallel/vector computers.

| P | muls | adds | P | muls | adds | P | muls | adds |  |

## Chapter 8

## Conclusion ${ }^{1}$

### 8.1 Conclusion

We have found that by using the split nesting algorithm for circular convolution a new set of efficient prime length DFT modules that cover a wide variety of lengths can be developed. We have also exploited the structure in the split nesting algorithm to write a program that automatically generates compact readable code for convolution and prime length FFT programs.

The resulting code makes clear the organization and structure of the algorithm and clearly enumerates the disjoint convolutions into which the problem is decomposed. These independent convolutions can be executed in parallel and, moreover, the individual commands are of the form $I \otimes A \otimes I$ which can be executed as parallel/vector commands on appropriate computer architectures[37]. By recognizing also that the algorithms for different lengths share many of the same computational structures, the code we generate is made up of calls to a relatively small set of functions. Accordingly, the subroutines can be designed to specifically suit a given architecture.

The number of additions and multiplications incurred by the programs we have generated are the same as or are competitive with existing prime length FFT programs. We note that previously, prime length FFTs were made available for primes only up to 29 . As in the original Winograd short convolution algorithms, the efficiency of the resulting prime $p$ point DFT algorithm depends largely upon the factorability of $p-1$. For example, if $p-1$ is two times a prime, then an efficient $p$ point DFT algorithm is more difficult to develop.

It should be noted too that the programs for convolution developed above are useful in the convolution of long integer sequences when exact results are needed. This is because all multiplicative constants in an $n$ point integer convolution are integer multiples of $1 / n$ and this division by $n$ can be delayed until the last stage or can simply be omitted if a scaled version of the convolution is acceptable.

By developing a large library of prime point FFT programs we can extend the maximum length and the variety of lengths of a prime factor algorithm or a Winograd Fourier transform algorithm. Furthermore, because the approach taken in this paper gives a bilinear form, it can be incorporated into the dynamic programming technique for designing optimal composite length FFT algorithms [10]. The programs described in this paper can also be adapted to obtain discrete cosine transform (DCT) algorithms by simply permuting the input and output sequences [8].

[^8]
## Chapter 9

## Appendix: Bilinear Forms for Linear Convolution

### 9.1 Appendix: Bilinear Forms for Linear Convolution

The following is a collection of bilinear forms for linear convolution. In each case ( $D_{n}, D_{n}, F_{n}$ ) describes a bilinear form for $n$ point linear convolution. That is

$$
\begin{equation*}
y=F_{n}\left\{D_{n} h * D_{n} x\right\} \tag{9.1}
\end{equation*}
$$

computes the linear convolution of the $n$ point sequences $h$ and $x$.
For each $D_{n}$ we give Matlab programs that compute $D_{n} x$ and $D_{n}^{t} x$, and for each $F_{n}$ we give a Matlab program that computes $F_{n}^{t} x$. When the matrix exchange algorithm is employed in the design of circular convolution algorithms, these are the relevant operations.

### 9.1.1 2 point linear convolution

$D_{2}$ can be implemented with 1 addition, $D_{2}^{t}$ with two additions.

$$
\begin{gather*}
D_{2}=\left[\begin{array}{ll}
1 & 0 \\
0 & 1 \\
1 & 1
\end{array}\right]  \tag{9.2}\\
F_{2}=\left[\begin{array}{ccc}
1 & 0 & 0 \\
-1 & -1 & 1 \\
0 & 1 & 0
\end{array}\right] \tag{9.3}
\end{gather*}
$$

```
function y = D2(x)
y = zeros(3,1);
y(1) = x(1);
y(2) = x(2);
y(3) = x(1) + x(2);
```

[^9]```
function y = D2t(x)
y = zeros(2,1);
y(1) = x(1)+x(3);
y(2) = x (2)+x(3);
function y = F2t(x)
y = zeros(3,1);
y(1) = x(1)-x(2);
y(2) = -x(2)+x(3);
y(3) = x(2);
```

### 9.1.2 3 point linear convolution

$D_{3}$ can be implemented in 7 additions, $D_{3}^{t}$ in 9 additions.

$$
\begin{gather*}
D_{3}=\left[\begin{array}{ccc}
1 & 0 & 0 \\
1 & 1 & 1 \\
1 & -1 & 1 \\
1 & 2 & 4 \\
0 & 0 & 1
\end{array}\right]  \tag{9.4}\\
F_{3}=\frac{1}{6}\left[\begin{array}{ccccc}
6 & 0 & 0 & 0 & 0 \\
-3 & 6 & -2 & -1 & 12 \\
-6 & 3 & 3 & 0 & -6 \\
3 & -3 & -1 & 1 & -12 \\
0 & 0 & 0 & 0 & 6
\end{array}\right] \tag{9.5}
\end{gather*}
$$

```
function y = D3(x)
y = zeros(5,1);
a = x(2)+x(3);
b = x (3) -x(2);
y(1) = x(1);
y(2) = x(1)+a;
y(3) = x(1)+b;
y(4) = a+a+b+y(2);
y(5) = x(3);
function y = D3t(x)
y = zeros(3,1);
y(1) = x (2)+x(3)+x(4);
a = x(4)+x(4);
y(2) = x(2)-x(3)+a;
y(3) = y(1)+x(4)+a;
```

```
y(1) = y(1)+x(1);
y(3) = y(3)+x(5);
function y = F3t(x)
y = zeros(5,1);
y(1) = 6*x(1) -3*x (2) -6*x (3)+3*x(4);
y(2) = 6*x(2)+3*x(3)-3*x(4);
y(3) = -2*x(2)+3*x(3)-x(4);
y(4) = -x(2)+x(4);
y(5) = 12*x(2)-6*x(3)-12*x(4)+6*x(5);
y = y/6;
```

### 9.1.3 4 point linear convolution

$$
\begin{gather*}
D_{4}=D_{2} \otimes D_{2}  \tag{9.6}\\
F_{4}=\left[\begin{array}{ccccccccc}
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
-1 & -1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
-1 & 1 & 0 & -1 & 0 & 0 & 1 & 0 & 0 \\
1 & 1 & -1 & 1 & 1 & -1 & -1 & -1 & 1 \\
0 & -1 & 0 & 1 & -1 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & -1 & -1 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0
\end{array}\right] \tag{9.7}
\end{gather*}
$$

```
function y = F4t(x)
y = zeros(7,1);
y(1) = x(1)-x(2)-x(3)+x(4);
y(2) = -x(2)+x(3)+x(4)-x(5);
y(3) = x(2)-x(4);
y(4) = -x(3)+x(4)+x(5)-x(6);
y(5) = x(4)-x(5) -x(6)+x(7);
y(6) = -x(4)+x(6);
y(7) = x (3) -x(4);
y(8) = -x(4)+x(5);
y(9) = x(4);
```

### 9.1.4 6 point linear convolution

$$
\begin{equation*}
D_{6}=D_{2} \otimes D_{3} \tag{9.8}
\end{equation*}
$$

$$
F_{6}=\frac{1}{6}\left[\begin{array}{ccccccccccccccc}
6 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0  \tag{9.9}\\
-3 & 6 & -2 & -1 & 12 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\

## Appendix: Matlab Functions For Circular Convolution and Prime Length FFTs'

### 12.1 Programs for Reduction Operations

The reduction matrix of Equation 44 in Preliminaries (2.44) is implemented by KRED which calls RED . Its transpose and inverse transpose are implemented by tRED, tRED, itKRED and itRED.

```
    function x = KRED(P,E,K,x)
% x = KRED(P,E,K,x);
% P : P = [P(1),...,P(K)];
% E : E = [E(K),...,E(K)];
for i = 1:K
    a = prod(P(1:i-1).^E(1:i-1));
    c = prod(P(i+1:K).^E(i+1:K));
    p = P(i);
    e = E(i);
    for j = e-1:-1:0
        x(1:a*c*(p^(j+1))) = RED(p,a,c*(p^j),x(1:a*c*(p^(j+1))));
    end
end
function y = RED(p,a,c,x)
% y = RED(p,a,c,x);
y = zeros(a*c*p,1);
for i = 0:c:(a-1)*c
    for j = 0:c-1
        y(i+j+1) = x(i*p+j+1);
        for k = 0:c:c*(p-2)
                y(i+j+1) = y(i+j+1) + x(i*p+j+k+c+1);
                y(i*(p-1)+j+k+a*c+1) = x(i*p+j+k+1) - x(i*p+j+c*(p-1)+1);
            end
    end
end
```

[^12]```
    function x = tKRED(P,E,K,x)
% x = tKRED(P,E,K,x);
% (transpose)

        end
    end
end
```

### 12.2 Programs for $\mathbf{I} \otimes \mathbf{D k} \otimes \mathbf{I}$

The operations of $I_{m} \otimes D_{2} \otimes I_{n}$ and $I_{m} \otimes D_{3} \otimes I_{n}$ are carried out by ID2I and ID3I. Their transposes by ID2tI and ID3tI. The functions D2 and D3 are listed in the appendix, 'Bilinear Forms for Linear Convolution.' Two versions of ID2I are listed here. One of them calls D2 in a loop, while the other version puts the D2 code in the loop instead of using a function call. There are several ways to implement the form $I \otimes D_{2} \otimes I$. But this is a simple and straightforward method. It is modeled after IAI in the text.

```
    function y = ID2I(m,n,x)
y = zeros(m*n*3,1);
v = 0:n:2*n;
u = 0:n:n;
for i = 0:m-1
    for j = 0:n-1
        y(v+i*3*n+j+1) = D2 (x (u+i*2*n+j+1));
    end
end
```

```
    function y = ID2I(m,n,x)
y = zeros(m*n*3,1);
for i = 0:n:n*(m-1)
    i2 = 2*i;
```

```
    i3 = 3*i;
    for j = 1:n
        j2 = i2 + j;
        j3 = i3 + j;
        y(j3) = x(j2);
        y(n+j3) = x(n+j2);
        y(2*n+j3) = x(j2) + x (n+j2);
        end
end
    function y = ID2tI(m,n,x)
y = zeros(m*n*2,1);
v = 0:n:n;
u = 0:n:2*n;
for i = 0:m-1
    for j = 0:n-1
        y(v+i*2*n+j+1) = D2t (x(u+i*3*n+j+1));
    end
end
    function y = ID3I(m,n,x)
y = zeros(m*n*5,1);
v = 0:n:4*n;
u = 0:n:2*n;
for i = 0:m-1
    for j = 0:n-1
        y(v+i*5*n+j+1) = D3 (x (u+i*3*n+j+1));
    end
end
    function y = ID3tI(m,n,x)
y = zeros(m*n*3,1);
v = 0:n:2*n;
u = 0:n:4*n;
for i = 0:m-1
    for j = 0:n-1
        y(v+i*3*n+j+1) = D3t (x(u+i*5*n+j+1));
    end
end
```

### 13.1 Programs for Computing Multiplicative Constants

The following programs carry out the operation of $F_{d_{1}} \otimes \cdots \otimes F_{d_{K}}$ where $F$ is the reconstruction matrix in a linear convolution algorithm. See the appendix, 'Bilinear Forms for Linear Convolution.'

```
    function u = KFt(f,r,c,u)
% u = (F^t kron ... kron F^t)*u
% (transpose)
% f = [f(1),...,f(K)]
% r : r(i) = rows of F(i)
% c : c(i) = columns of F(i)
% u : length(u) = prod(c);
K = length(f);
for i = 1:K
    m = prod(c(1:i-1));
    n = prod(r(i+1:K));
    u = IFtI(f(i),r(i),c(i),m,n,u);
end
    function y = IFtI(s,r,c,m,n,x);
% y = (I(m) kron F(s)^t kron I (n))*x
% (transpose)
% r : rows of F(s)
% c : columns of F(s)
v = 0:n:n*(c-1);
u = 0:n:n*(r-1);
for i = 0:m-1
    for j = 0:n-1
        y(v+i*c*n+j+1) = Ftop(s,x(u+i*r*n+j+1));
    end
end
    function y = Ftop(k,x)
if k == 1, y = x;
elseif k == 2, y = F2t(x);
elseif k == 3, y = F3t(x);
elseif k == 4, y = F4t(x);
elseif k == 6, y = F6t(x);
elseif k == 8, y = F8t(x);
elseif k == 18, y = F18t(x);
end
```

The following programs carry out the operation of $G_{p_{1}^{e_{1}}} \otimes \cdots \otimes G_{p_{K}^{e_{K}}}$ were $G$ is given by Equation 13 (3.13) and Equation 14 from Bilinear Forms for Circular Convolution (3.14).

```
    function x = Kcrot(p,e,K,x)
% Kronecker product of Cyclotomic Reduction Operations.
% x = (G(p(1)^e(1)) kron ... kron G(p(K)^(K)))^t*x
% (transpose)
% p : p = [p(1),...,p(K)];
% e : e = [e(1),...,e(K)];
a = (p-1).*((p).^(e-1));
```

```
r = a; % r(i) = number of rows of G(i)
c = 2*a-1; % c(i) = number of columns of G(i)
m = 1;
n = prod(r);
for i = 1:K
    n = n / r(i);
    x = IcrotI(p(i),e(i),m,n,x);
    m = m * c(i);
end
    function y = IcrotI(p,e,m,n,x)
% y = (eye(m) kron G(p`e)^t kron eye(n))*x
% (transpose)
a = (p-1)*(p^(e-1));
c = a;
r = 2*a-1;
y = zeros(r*m*n,1);
v = 0:n:(r-1)*n;
u = 0:n:(c-1)*n;
for i = 0:m-1
    for j = 0:n-1
        y(v+i*r*n+j+1) = crot(p,e,x(u+i*c*n+j+1));
    end
end
    function y = crot(p,e,x)
% y = crot(p,x)
% cyclotomic reduction matrix (transpose)
% length(x) == 2*n-1
% length(y) == n
% where n = (p-1)*(p^(e-1))
n = (p-1)*(p^(e-1));
y = zeros(2*n-1,1);
if p == 2
    n = p^(e-1);
    y(1:n) = x;
    y(n+1:2*n-1) = -x(1:n-1);
else
    y(1:n) = x;
    L = p^(e-1);
    y(n+1:n+L) = -x(1:L);
    a = L;
    for k = 2:p-1
        y(n+1:n+L) = y(n+1:n+L) - x(a+1:a+L);
        a = a + L;
    end
    b = 2*n-1 - p*(p^(e-1));
    y(p*L+1:p*L+b) = x (1:b);
end
```

The following programs tell the programs for code generation relevant information about the bilinear forms for cyclotomic convolution. Specifically, they indicates the linear convolution out of which these cyclotomic
convolution are composed, and the dimensions of the corresponding matrices. See the appendix Bilinear Forms for Linear Convolution (Chapter 9).

```
        function [d,r,c,Q,Qt] = A_data(n)
% A : A matrix in bilinear form for cyclotomic convolution

elseif n == 2, c = 3;
elseif n == 4, c = 9;
```

```
elseif n == 8, c = 27;
elseif n == 3, c = 5;
elseif n == 6, c = 15;
elseif n == 18, c = 75;
end
```

### 13.1.1 Programs for Inverse Transpose Reduction Operations

```
    function x = itKRED(P,E,K,x)
% x = itKRED(P,E,K,x);
% (inverse transpose)
% P : P = [P(1),...,P(K)];
% E : E = [E(K),...,E(K)];
for i = 1:K
    a = prod(P(1:i-1).^E(1:i-1));
    c = prod(P(i+1:K).^E(i+1:K));
    p = P(i);
    e = E(i);
    for j = e-1:-1:0
        x(1:a*c*(p^(j+1))) = itRED(p,a,c*(p^j),x(1:a*c* (p^(j+1))));
    end
end
    function y = itRED(p,a,c,x)
% y = itRED(p,a,c,x);
% (inverse transpose)
y = zeros(a*c*p,1);
for i = 0:c:(a-1)*c
    for j = 0:c-1
        A = x (i*p+j+1);
        for k = 0:c:c*(p-2)
            A = A + x (i*p+j+k+c+1);
        end
        y(i+j+1) = A;
        for k = 0:c:c*(p-2)
            y(i*(p-1)+j+k+a*c+1) = p*x(i*p+j+k+1) - A;
        end
    end
end
y = y/p;
```

### 13.2 Programs for Permutations

The permutation of Equation 18 from Preliminaries (2.18) is implemented by pfp. It calls the function pfp2I. The transpose is implemented by pfpt and it calls pfpt2I.

```
    function x = pfp(n,K,x)
% x = P(n(1),...,n(K)) * x
% n = [n(1),...,n(K)];
% length(x) = prod(n(1),...,n(K))
```

```
a = prod(n);
s = 1;
for i = K:-1:2
    a = a / n(i);
    x = pfp2I(a,n(i),s,x);
    s = s * n(i);
end
```

function $y=\operatorname{pfp} 2 I(a, b, s, x)$
$\% \mathrm{y}=\operatorname{kron}(\mathrm{P}(\mathrm{a}, \mathrm{b}), \mathrm{I}(\mathrm{s})) * \mathrm{x}$;
$\%$ length $(x)=a * b * s$
$\mathrm{n}=\mathrm{a} * \mathrm{~b}$;
$\mathrm{y}=\operatorname{zeros}(\mathrm{n} * \mathrm{~s}, 1)$;
$\mathrm{k} 1=0$;
k2 = 0;
for $k=0: n-1$
$\mathrm{i} 1 \mathrm{~s}=\mathrm{s}(\mathrm{k} 1+\mathrm{b} * \mathrm{k} 2)$;
i2 = s * k;
for $\mathrm{i}=1: \mathrm{s}$
$y(i 1+i)=x(i 2+i) ;$
end
$\mathrm{k} 1=\mathrm{k} 1+1$;
$\mathrm{k} 2=\mathrm{k} 2+1$;
if $\mathrm{k} 1>=\mathrm{b}$
k 1 = k1 - b;
end
if k2 $>=\mathrm{a}$
$\mathrm{k} 2 \mathrm{=}$ k2 - a ;
end
end
function $x=\operatorname{pfpt}(n, K, x)$
$\% \mathrm{x}=\mathrm{P}(\mathrm{n}(1), \ldots, \mathrm{n}(\mathrm{K}))$ ) * x
\% (tanspose)
$\% \mathrm{n}=[\mathrm{n}(1), \ldots, \mathrm{n}(\mathrm{K})]$;
$\% \operatorname{length}(x)=\operatorname{prod}(n(1), \ldots, n(K))$
$\% \quad \mathrm{a}=\operatorname{prod}(\mathrm{n})$;
$\mathrm{a}=\mathrm{n}(1)$;
$\mathrm{s}=\operatorname{prod}(\mathrm{n}(2: K))$;
for $i=2: K$
$\mathrm{s}=\mathrm{s} / \mathrm{n}(\mathrm{i})$;
$\mathrm{x}=\mathrm{pfpt} 2 \mathrm{I}(\mathrm{a}, \mathrm{n}(\mathrm{i}), \mathrm{s}, \mathrm{x})$;
$\mathrm{a}=\mathrm{a} * \mathrm{n}(\mathrm{i})$;
end
function $y=\operatorname{pfpt} 2 I(a, b, s, x)$
$\% \mathrm{y}=\mathrm{P}(\mathrm{a}, \mathrm{b})$, kron $\mathrm{I}(\mathrm{s}) * \mathrm{x}$;
\% (transpose)
\% length (x) = a*b*s
$\mathrm{n}=\mathrm{a} * \mathrm{~b}$;
$\mathrm{y}=\operatorname{zeros}(\mathrm{n} * \mathrm{~s}, 1)$;

```
\(\mathrm{k} 1=0\);
\(\mathrm{k} 2=0\);
for \(k=0: n-1\)
    \(i 1=s *(k 1+b * k 2)\);
    i 2 = s * k ;
    for \(\mathrm{i}=1: \mathrm{s}\)
        \(y(i 2+i)=x(i 1+i) ;\)
    end
    \(\mathrm{k} 1=\mathrm{k} 1+1\);
    k 2 = k2 + 1;
    if \(\mathrm{k} 1>=\mathrm{b}\)
        \(\mathrm{k} 1=\mathrm{k} 1-\mathrm{b}\);
    end
    if k2 \(>=\mathrm{a}\)
        \(\mathrm{k} 2=\mathrm{k} 2-\mathrm{a}\);
    end
end
```

The following Matlab programs implement Rader's permutation and its transpose. They require the primitive root to be passed to them as an argument.

```
        function y = rp(p,r,x)
% Rader's Permutation
% p : prime
% r : a primitive root of p
% x : length(x) == p
a = 1;
y = zeros(p,1);
y(1) = x(1);
for k = 2:p
    y(k) = x (a+1);
    a = rem(a*r,p);
end
    function y = rpt(p,r,x)
% Rader's Permutation
% (transpose)
% p : prime
% r : a primitive root of p
% x : length(x) == p
a = 1;
y = zeros(p,1);
y(1) = x(1);
for k = 2:p
    y(a+1) = x(k);
    a = rem(a*r,p);
end
    function [R, R_inv] = primitive_root(N)
% function [R, R_inv] = primitive_root(N)
% Ivan Selesnick
```

```
% N is assumed to be prime. This function returns R,
% the smallest primitive root of N, and R_inv, the
% inverse of R modulo N.
R = 'Not Found';
m = 0:(N-2);
for x = 1:(N-1)
    if ( 1:(N-1) == sort(rem2(x,m,N)) )
        R = x;
        break
    end
end
R_inv = 'Not Found';
for x = 1:N
    if rem(x*R,N) == 1
        R_inv = x;
        break
    end
end
```

## Automatic Generation of Prime Length FFT Programs

This collection of modules is from a Rice University, ECE Department Technical Report written around September 1994. It grew out of the doctoral and post doctoral research of Ivan Selesnick working with Prof. C. Sidney Burrus at Rice. Earlier reports on this work were published in the ICASSP and ISCAS conference proceedings in 1992-94 and a fairly complete report was published in the IEEE Transaction on Signal Processing in January 1996.

## About Connexions

Since 1999, Connexions has been pioneering a global system where anyone can create course materials and make them fully accessible and easily reusable free of charge. We are a Web-based authoring, teaching and learning environment open to anyone interested in education, including students, teachers, professors and lifelong learners. We connect ideas and facilitate educational communities.
Connexions's modular, interactive courses are in use worldwide by universities, community colleges, K-12 schools, distance learners, and lifelong learners. Connexions materials are in many languages, including English, Spanish, Chinese, Japanese, Italian, Vietnamese, French, Portuguese, and Thai. Connexions is part of an exciting new information distribution system that allows for Print on Demand Books. Connexions has partnered with innovative on-demand publisher QOOP to accelerate the delivery of printed course materials and textbooks into classrooms worldwide at lower prices than traditional academic publishers.
