References with identical names in the java:global, java:app, or java:module namespaces might conflict with each other, just as references with identical names in the component namespace might conflict. A reference scoped to the java:app namespace for one application does not conflict with an identically named reference scoped to the java:app namespace for a different application. Likewise, a reference scoped to the java:module namespace for one module does not conflict with an identically named reference scoped to the java:module namespace for a different module.

A reference can be declared in the java:global namespace using annotations; for example:

```
@EJB(name="java:global/env/myBean")
```

A reference can be declared in the ejb-jar.xml file; for example:

```
<resource-ref>
    <res-ref-name>java:global/env/myDataSource</res-ref-name>
    ....
</resource-ref>
```

For additional documentation on the java:[scope] namespaces, see section 5.2.2 of the Java EE 6 specification and section 4.4 of the Enterprise JavaBeans 3.1 specification.

## User-defined bindings for EJB business interfaces, homes, and no-interface views

For cases where you want to manually assign binding locations rather than using the product default bindings, you can use the EJB module binding file to assign your own binding locations to specific interfaces, homes, and no-interface views. You can also use this file to only override the component ID portion of the default bindings on one or more enterprise beans in the module. Overriding the component ID provides a middle ground between using all default bindings and completely specifying the binding name for each interface or no-interface view.

**Note:** To specify user-defined bindings information for EJB 3.x modules, place the file ibm-ejb-jar-bnd.xml, in the META-INF directory for the EJB Java archive (JAR) file. The suffix on this file is XM**L**, not XM**I**, as in prior versions of product.

Also, when defining a classic binding for a local interface or no-interface view, you must preface the name with the string "ejblocal:" so it is bound into the classic JVM-scoped ejblocal: namespace.

The ibm-ejb-jar-bnd.xml file is used for EJB 3.0 and later modules that run on the product, whereas the `ibm-ejb-jar.bnd.xmi` file is used for pre-EJB 3.0 modules and for web modules. The binding file format in the `ibm-ejb-jar.bnd.xml` file is different from the XMI file format for the following reasons:

- Bindings and extensions that are declared in the XMI file format depend on the presence of a corresponding `ejb-jar.xml` deployment descriptor file that explicitly refers to unique ID numbers that are attached to elements in that file. This system is no longer viable for EJB 3.0 and later modules, where it is no longer a requirement for the module to contain an `ejb-jar.xml` deployment descriptor.
- The XMI file format was designed to be machine-edited only by the product development tools and system management functions; it was effectively part of the internal implementation of the product and the file structure was never documented externally. This made it impossible for developers to manually edit binding files, or create them as part of a WebSphere independent build process, in a supported way.
- Rather than referring to encoded ID numbers in the `ejb-jar.xml` deployment descriptor, the XML-based binding file refers to an EJB component by its EJB name. Each EJB component in a module has a unique EJB name, either by default or through explicit assignment by the developer. Therefore, this behavior provides an unambiguous way to target bindings and extensions.
- The new binding files are XML-based, and an XML Schema Definition (XSD) file is provided to externally document the structure. These `.xsd` files can be consumed by many common XML file editors to assist in syntactic verification and code completion functions. As a result, it is now possible for developers to produce and edit the binding and extension files independently of the application server infrastructure.

The following table lists the ibm-ejb-jar-bnd.xml elements and attributes that are used to assign bindings to EJB interfaces and homes for EJB 3.x modules and no-interface views for EJB 3.1 modules.

*Table 86. ibm-ejb-jar-bnd.xml elements and attributes.* ibm-ejb-jar-bnd.xml *elements and attributes*

| Element or attribute | How used | Example | Comments |
|---|---|---|---|
| <session> | Declares a group of binding assignments for a session bean. | <session name="AccountServiceBean"/> | Requires name attribute and at least one of the following attributes: simple-binding-name attribute, local-home-binding-name attribute, remote-home-binding-name attribute, or <interface> element. |
| name | Attribute that identifies the ejb-name of the enterprise bean that a <session>, <message-driven>, or <entity>, or other element applies to. | <session name="AccountServiceBean"/> | The name value is the name declared in the <ejb-name> element of an ejb-jar.xml deployment descriptor file, the name attribute of a @Stateful, @Stateless, @Singleton, or @MessageDriven annotation, or defaults to the unqualified class name of the EJB implementation class annotated with the @Session or @MessageDriven annotation (if no <ejb-name> value is declared in the XML deployment descriptor and no name parameter is declared on the annotation). |
| component-id | Attribute that overrides the default component ID value for an enterprise bean. The default long-form classic bindings for this enterprise bean uses the specified component ID instead of *<app_name>/<module_jar_name>/<bean_name>*. | <session name="AccountServiceBean" component-id="Dept549/AccountProcessor"/><br><br>The previous example results in the bean whose ejb-name is AccountServiceBean, having its long-form default classic local interfaces bound at ejblocal:Department549/AccountProcessor#*<package.qualified.interface>* Its long-form default classic remote interfaces are bound at ejb/Department549/AccountProcessor#*<package.qualified.interface>* | Can be used alone, or in combination with the <interface> element, the local-home-binding-name attribute, or the remote-home-binding-name attribute. Interfaces that are not assigned explicit bindings might have default classic bindings performed using the user-specified component ID value. Interfaces that are assigned explicit bindings are bound using those values.<br><br>Since the simple-binding-name attribute is intended to apply to all defined interfaces on a given enterprise bean (leaving no interfaces defaulted), applying a component-id in combination with a simple-binding-name is typically not useful. |

*Table 86. `ibm-ejb-jar-bnd.xml` elements and attributes (continued). `ibm-ejb-jar-bnd.xml` elements and attributes*

| Element or attribute | How used | Example | Comments |
|---|---|---|---|
| simple-binding-name | A simple mechanism for assigning interface bindings for Enterprise JavaBeans that:<br>• Implement a single EJB 3.x business interface<br>• Implement a pre-EJB 3.0 style component interface (local, remote or both types) with a companion EJB home.<br>The value of the attribute is used as the binding location of the enterprise bean business interface, or the binding location of the Enterprise JavaBeans local, remote homes, or both. The binding is placed in the classic ejblocal: namespace if the interface or home is local, and placed in the root context of the application server of the classic globally scoped JNDI namespace if the interface or home is remote. | `<session name="AccountServiceBean" simple-binding-name="ejb/AccountService"/>`<br><br>This example results in the bean whose ejb-name is AccountServiceBean, having its local business interface or home, if any, bound at ejblocal:ejb/AccountService in the classic local JVM-scoped EJB namespace, and its remote business interface or home (if any) bound at ejb/AccountService in the root context of the application server of the classic globally scoped JNDI namespace. **Important:** The exact value of the attribute, including, in this specific example, the "ejb" subcontext name is used even if the interface is a local interface bound into the ejblocal: namespace. When user-defined bindings are specified, the exact name specified by the attribute is used.) | Not to be used in combination with local-home-binding-name or remote-home-binding-name attributes, or the <interface> element. Also, must not be used on beans that implement more than one business interface - use the <interface> element in that case instead.<br><br>If this attribute is used on an enterprise bean that implements more than one business interface, or a combination of business interface and local/remote component interface with home, the resulting bindings are disambiguated by appending a hash or number sign (# symbol) to the attribute value, followed by the package-qualified class name of each interface, home, or both on the enterprise bean. This condition can be avoided, however, by using the <interface> element to define a binding for each of the business interfaces instead of using simple-binding-name.<br><br>**Important:** defining a simple-binding-name on a bean that implements more than one business interface is not the same as overriding the default component ID for a bean using <component-id>. Remote interface default bindings defined with a component-id are still grouped under the EJB context (as all remote interface default bindings are), while remote interface bindings disambiguated by the EJB container in response to erroneous use of simple-binding-name on a bean with multiple interfaces are not grouped under the ejb context. Additionally, the inclusion of the package-qualified class name always occurs for long-form default classic bindings, whereas with simple-binding-name it occurs only on error conditions, where disambiguation is necessary. Do not depend on the binding name created through disambiguation, since whether that effect occurs might change if the bean is changed to implement more or fewer interfaces. |
| local-home-binding-name | Attribute to specify the binding location of the local home of an enterprise bean. | `<session name="AccountServiceBean" local-home-binding-name="ejblocal:AccountService"/>` | Not to be used in combination with the simple-binding-name attribute. Since local homes must always be bound into the classic JVM-scoped namespace, the value must begin with the ejblocal: prefix. |

*Table 86. ibm-ejb-jar-bnd.xml elements and attributes (continued). ibm-ejb-jar-bnd.xml elements and attributes*

| Element or attribute | How used | Example | Comments |
|---|---|---|---|
| remote-home-binding-name | Attribute to specify the binding location of the remote home of an enterprise bean. | <session name="AccountServiceBean"<br>remote-home-binding-name=<br>"ejb/services/AccountService"/> | Not to be used in combination with the simple-binding-name attribute. The value cannot begin with the classic ejblocal: prefix, since remote homes cannot be bound into the classic ejblocal: namespace. |
| <interface> | A subelement of the <session> element that assigns a binding to a specific EJB business interface or no-interface view. In contrast to the simple-binding-name, local-home-binding-name and remote-home-binding-name attributes, both a binding-name parameter and a class parameter are necessary (in fact, this distinction is why a separate XML element is necessary rather than an attribute). The class parameter specifies the package-qualified name of the business interface or no-interface view class to be bound. | <interface class="com.ejbs.InventoryService"<br>binding-name="ejb/Inventory"/><br><br>(declared as a subelement inside a <session> element) | Not to be used in combination with the simple-binding-name attribute. Since local interfaces and no-interface views must always be bound into the classic JVM-scoped namespace, the binding-name value must begin with the ejblocal: prefix when this element is applied to a local interface or no-interface view. |
| binding-name | Attribute to specify the binding location of a business interface bound with the <interface> element. | <interface class="com.ejbs.InventoryService"<br>binding-name="ejb/Inventory"/><br><br>(declared as a subelement inside a <session> element) | Required in combination with the <interface> element (and used on that element only). Since local interfaces must always be bound into the classic JVM-scoped namespace, the binding-name value must begin with the ejblocal: prefix when applied to a local interface. |

### Binding file Example 1

The following example is a basic ibm-ejb-jar-bnd.xml file that contains only the elements and attributes that assign binding names to EJB interfaces and no-interface views. It overrides the component ID used for default bindings on the enterprise bean that is named *S01*, and assigns explicit bindings to some of the interfaces on the enterprise beans, *S02* and *S03*, in this module.

```
<?xml version="1.0" encoding="UTF-8"?>
<ejb-jar-bnd xmlns="http://websphere.ibm.com/xml/ns/javaee" xmlns:xsi="
 http://www.w3.org/2001/XMLSchema-instance"xsi:schemaLocation="
 http://websphere.ibm.com/xml/ns/javaee
 http://websphere.ibm.com/xml/ns/javaee/ibm-ejb-jar-bnd_1_0.xsd "version "1.0">
 <session name="S01" component-id="Department549/AccountProcessors"/>
 <session name="S02" simple-binding-name="ejb/session/S02"/>
 <session name="S03">
  <interface class="com.ejbs.BankAccountService" binding-name="ejblocal:session/BAS"/>
 </session>
</ejb-jar-bnd>
```

The binding file has the following results:

- The session bean with ejb-name *S01* is assigned a user-defined component ID, overriding the default component ID (application name/ejb-jar module name/bean name) for all interfaces and no-interface views on that bean. Local interfaces and no-interface views on this bean are bound at ejblocal:Department549/AccountProcessors#<*package.qualified.interface.name*> while remote interfaces are bound at ejb/Department549/AccountProcessors#<*package.qualified.interface.name*>
- The session bean with ejb-name *S02* is assumed to have a single EJB 3.x business interface or EJB 3.1 no-interface view. Alternatively, it could have a pre-EJB 3.0 "component" interface with local home, remote home, or both local and remote homes. The business interface, or the home or homes of the component interface are bound at ejblocal:ejb/session/S02 if it is local, or ejb/session/S02 if it is remote.

If bean *S02* has more than one business interface, or business interfaces and home, a simple-binding-name is ambiguous. In that case, the container disambiguates the binding assignments by appending #<*package.qualified.interface.name*> to the simple binding name, ejb/session/S02, for each of the bean interfaces.

- The EJB 3.x business interface or EJB 3.1 no-interface view, com.ejbs.BankAccountService, on the session bean with ejb-name *S03* is bound at ejblocal:session/BAS.

All other business interfaces, homes, and no-interface views on this bean, if present, are assigned default classic bindings. The com.ejbs.BankAccountService interface is assumed to be local since it was designated for the ejblocal: namespace in this example; an error occurs if the interface is not local.

The next section expands on this example, introducing elements for resolving the targets of various kinds of reference and injection entries that are declared either in the XML deployment descriptor or through annotations.

## User-defined bindings for resolving references and injection targets

The previous section showed examples of assigning user-defined binding names for business interfaces, homes, and no-interface views. This section covers resolving linkage targets for references, injection directives, and message-driven bean destinations.

*Table 87. Elements and attributes to resolve linkage targets for references and injection targets. Elements and attributes to resolve linkage targets for references and injection targets*

| Element or attribute | How used | Example | Comments |
|---|---|---|---|
| <jca-adapter> | Defines the JCA 1.5 adapter activation spec, and a message-destination JNDI location, for delivery of messages to a message-driven bean. | `<jca-adapter activation-spec-binding-name="jms/InternalProviderSpec" destination-binding-name="jms/ServiceQueue"/>` | Requires *activation-spec-binding-name* attribute. If the corresponding message-drive bean does not identify its message destination by using the <message-destination-link> element, then the *destination-binding-name* attribute is also required. Can optionally include activation-spec-auth-alias attribute. |
| <ejb-ref> | Resolves the target of an ejb-ref declaration, which is declared through the @EJB annotation or through the ejb-ref in the ejb-jar.xml deployment descriptor, providing the linkage between the name declared in the component-scoped java:comp/env namespace and the name of the target enterprise bean in the classic JVM-scoped ejblocal:, or classic globally scoped JNDI namespace. | `<ejb-ref name="com.ejbs.BankAccountServiceBean/s02Ref" binding-name="ejb/session/S02"/>` | Requires the name and binding-name attributes. |
| <message-driven> | Declares a group of binding assignments for a message-driven bean. | `<message-driven name="EventRecorderBean"> <jca-adapter activation-spec-binding-name="jms/InternalProviderSpec" destination-binding-name="jms/ServiceQueue"/> </message-driven>` | Requires name attribute and <jca-adapter> subelement. |

*Table 87. Elements and attributes to resolve linkage targets for references and injection targets (continued).*
*Elements and attributes to resolve linkage targets for references and injection targets*

| Element or attribute | How used | Example | Comments |
|---|---|---|---|
| <message-destination> | Associates the name of a message destination, which is a logical name defined in a Java EE module deployment descriptor, with a specific global JNDI name, which is an actual name in the JNDI namespace. <message-destination-ref> elements in the Java EE module deployment descriptor, or @Resource injection directives that inject message destinations, can then use the <message-destination-line> element to refer to this message-destination by the destination logical name, rather than requiring individual <message-destination-ref> binding entries in the binding file for each defined message-destination-ref. | `<message-destination name="EventProcessingDestination" binding-name="jms/ServiceQueue"/>` | Requires name and binding-name attributes. |
| <message-destination-ref> | Resolves the target of a message-destination-ref declaration that is declared through the @Resource annotation or through the message-destination-ref in ejb-jar.xml, providing the linkage between the name declared in the component-scoped java:comp/env namespace and the name of the target resource environment in the global JNDI namespace. | `<message-destination-ref name="com.ejbs.BankAccountServiceBean/serviceQueue" binding-name="jms/ServiceQueue"/>` | Requires the name and binding-name attributes. |
| <resource-ref> | Resolves the target of a resource-ref declaration that is declared through the @Resource annotation or through resource-ref in ejb-jar.xml, providing the linkage between the name declared in the component-scoped java:comp/env namespace and the name of the target resource in the global JNDI namespace. | `<resource-ref name="com.ejbs.BankAccountServiceBean/dataSource" binding-name="jdbc/Default"/>` | Requires the name and binding-name attributes. Can include the authentication-alias or custom-login-configuration attributes. |
| <resource-env-ref> | Resolves the target of a resource-env-ref declaration that is declared through the @Resource annotation or through resource-env-ref in ejb-jar.xml, providing the linkage between the name declared in the component-scoped java:comp/env namespace and the name of the target resource environment in the global JNDI namespace. | `<resource-env-ref name="com.ejbs.BankAccountServiceBean/dataFactory" binding-name="jdbc/Default"/>` | Requires the name and binding-name attributes. |
| <env-entry> | Overrides an environment entry with the specified value represented in string format or object which can be accessed with a JNDI lookup on the specified lookup name applied to the default initial context. | `<env-entry name="java:module/env/taxYear" value="2010"/>` `<env-entry name="java:module/env/taxYear" binding-name="cell/persistent/MyApp/MyModule/taxYear"/` | Requires the name attribute and either the value or the binding-name attribute, but not both. |

*Table 87. Elements and attributes to resolve linkage targets for references and injection targets (continued).*
*Elements and attributes to resolve linkage targets for references and injection targets*

| Element or attribute | How used | Example | Comments |
|---|---|---|---|
| <data-source> | Overrides a data source definition, which is declared through the @DataSourceDefinition annotation or through the data-source element in the application, or a module deployment descriptor, with a managed resource. | `<data-source name="java:module/env/myDS" binding-name="jdbc/DB2DS"/>` | Requires the name and binding-name attributes. |
| name | Attribute that identifies the naming location, typically within the component-specific java:comp/env namespace, that defines the "source" side of a reference/target linkage, such as in ejb-ref, resource-ref, resource-env-ref, message-destination, or message-destination-ref. | `<ejb-ref name="com.ejbs.BankAccountServiceBean/goodBye" binding-name="ejb/session/S02"/>` | |
| binding-name | Attribute that identifies the naming location within the classic ejblocal: or classic globally scoped JNDI namespace, or java:global namespace that defines the "target" side of a reference/target linkage, such as in ejb-ref, resource-ref, resource-env-ref, message-destination, or message-destination-ref. | `<ejb-ref name="com.ejbs.BankAccountServiceBean/goodBye" binding-name="ejb/session/S02"/>` | |
| value | Attribute that specifies the value to use for an env-entry binding. | `<env-entry name="java:module/env/taxYear" value="2010"/>` | |
| activation-spec-binding-name | Attribute that identifies the JNDI location of the activation specification associated with the JCA 1.5 adapter to be used to deliver messages to a message-driven bean. | `<jca-adapter activation-spec-binding-name="jms/InternalProviderSpec" destination-binding-name="jms/ServiceQueue"/>` | This name must match the name of a JCA 1.5 activation specification that you define to WebSphere Application Server. |
| activation-spec-auth-alias | Optional attribute that identifies the name of a J2C authentication alias used for authentication of connections to the JCA resource adapter. A J2C authentication alias specifies the user ID and password that is used to authenticate the creation of a new connection to the JCA resource adapter. | `<jca-adapter activation-spec-binding-name="jms/InternalProviderSpec" activation-spec-auth-alias="jms/Service47Alias" destination-binding-name="jms/ServiceQueue"/>` | This name must match the name of a J2C authorization alias that you define to WebSphere Application Server |
| destination-binding-name | Attribute that identifies the JNDI name that the message-driven bean uses to look up its JMS destination in the JNDI name space. | `<jca-adapter activation-spec-binding-name="jms/InternalProviderSpec" destination-binding-name="jms/ServiceQueue"/>` | This name must match the name of a JMS queue or topic that you define to WebSphere Application Server. |
| authentication-alias | Optional subelement of the <resource-ref> binding element. If the resource reference is for a connection factory, then an optional JAAS login configuration can be specified; in this case a simple authentication alias name. | `<resource-ref name="com.ejbs.BankAccountServiceBean/dataSource" binding-name="jdbc/Default"> <authentication-alias name="defaultAuth"/> <resource-ref>` | This name must match the name of a JAAS authentication alias that you define to WebSphere Application Server. |
| custom-login-configuration | Optional subelement of the <resource-ref> binding element. If the resource reference is for a connection factory, then an optional JAAS login configuration can be specified; in this case a set of properties (name/value pairs). | `<resource-ref name="com.ejbs.BankAccountServiceBean/dataSource" binding-name="jdbc/Default"> <custom-login-configuration-name="customLogin"> <property name="loginParm1" value="ABC123"/> <property name="loginParm2" value="DEF456"/> </custom-login-configuration> </resource-ref>` | This name must match the name of a JAAS login configuration that you define to WebSphere Application Server. |

### Binding file Example 2

The following example is an expansion of the basic ibm-ejb-jar-bnd.xml file introduced in Example 1.

```
<?xml version="1.0" encoding="UTF-8"?>
<ejb-jar-bnd xmlns="http://websphere.ibm.com/xml/ns/javaee"xmlns:xsi="
http://www.w3.org/2001/XMLSchema-instance"
xsi:schemaLocation="http://websphere.ibm.com/xml/ns/javaee
http://websphere.ibm.com/xml/ns/javaee/ibm-ejb-jar-bnd_1_0.xsd"version "1.0">
 <session name="S01" component-id="Department549/AccountProcessors"/>
 <session name="S02" simple-binding-name="ejb/session/S02"/>
 <session name="S03">
  <interface class="com.ejbs.BankAccountService"
   binding-name="ejblocal:session/BAS"/>
  <ejb-ref name="com.ejbs.BankAccountServiceBean/goodBye"
   binding-name="ejb/session/S02"/>
  <resource-ref name="com.ejbs.BankAccountServiceBean/dataSource"
   binding-name="jdbc/Default"/>
 </session>
 <message-driven name="M01">
  <jca-adapter activation-spec-binding-name="jms/InternalProviderSpec"
   destination-binding-name="jms/ServiceQueue"/>
 </message-driven>
 <session name="S04" simple-binding-name="ejb/session/S04">
  <resource-ref name="ejbs.S04Bean/dataSource"
   binding-name="jdbc/Default">
   <authentication-alias name="defaultlogin"/>
  </resource-ref>
 </session>
 <session name="S05">
  <interface class="com.ejbs.InventoryService"
   binding-name="ejb/session/S05Inventory"/>
  <resource-ref name="ejbs.S05Bean/dataSource"
   binding-name="jdbc/Default">
   <custom-login-configuration name="customLogin">
    <property name="loginParm1" value="ABC123"/>
    <property name="loginParm2" value="DEF456"/>
   </custom-login-configuration>
  </resource-ref>
 </session>
</ejb-jar-bnd>
```

This binding has the following results:

1. The business interface, home, and no-interface view bindings for the session beans named S01, S02, and S03 are unchanged from the previous example.
2. The session bean whose ejb-name is *S03* now includes two reference target resolution bindings:
   - The ejb-ref binding resolves the EJB reference defined at java:comp/env/com.ejbs.BankAccountServiceBean/goodBye, to the JNDI location ejb/session/S02 within the root JNDI context of the application server. The EJB reference can also be defined by an @EJB injection in the class com.ejbs.BankAccountServiceBean, into an instance variable named "goodBye."

     **Note:** ejb/session/S02 is the JNDI location of session bean *S02* also defined in this same binding file, which means that the reference points to the session bean whose name is *S02*.
   - The resource-ref binding resolves the resource reference defined at java:comp/env/com.ejbs.BankAccountServiceBean/dataSource, to the JNDI location jdbc/Default. The resource reference could also have been defined by a @Resource injection in the class com.ejbs.BankAccountServiceBean, into an instance variable named "dataSource."
3. Bindings are defined for a message-driven bean whose ejb-name is *M01*. The MDB receives messages from a JMS destination defined to WebSphere Application Server, whose JNDI name is jms/ServiceQueue, using a JCA 1.5 adapter whose JCA 1.5 activation spec has been defined to WebSphere Application Server with the name jms/InternalProviderSpec.
4. The session bean whose ejb-name is *S04* is assumed to have a single business interface or no-interface view, which is bound at ejb/session/S04, if remote or ejblocal:ejb/session/S04, if local. It has a resource-ref with name, java:comp/env/ejbs/S04Bean/dataSource. This can also be the class, ejbs.S04Bean, with an @Resource injection into a variable named, dataSource. This resource-ref resolved to the JNDI location jdbc/Default. The resource-ref refers to a J2C connection and connects to this resource using a simple authentication alias named *defaultlogin* that has been defined in WebSphere Application Server.

5. A business interface binding is defined for the interface whose class name is com.ejbs.InventoryService implemented by the session bean whose ejb-name is *S05*; the interface is assumed to be remote since it is not prefixed with "ejblocal:" and might thus be bound at ejb/session/S05Inventory in the root JNDI context of the server in the classic globally-scoped namespace. Any other business interfaces implemented by this bean are assigned default classic bindings. The bean has a resource-ref with name java:comp/env/ejbs.S05Bean/dataSource (or a @Resource injection in the class ejbs.S05Bean into a variable named "dataSource") that is resolved to the JNDI location jdbc/Default. The resource-ref refers to a J2C connection and connects to this resource using a custom login configuration that includes two name-value pairs.

### Bindings file Example 3

This example demonstrates how to define and resolve EJB reference bindings to perform JNDI lookups across application server instances within the same WebSphere Application Server cell. It uses two EJB beans: a called bean that defines an explicit binding using the simple-binding-name attribute, and a calling bean that performs an @EJB injection and uses the ejb-ref element within its associated binding file to resolve the reference so it points at the called bean, that resides in a different application server process.

### ibm-ejb-jar-bnd.xml (called bean)

```
<?xml version="1.0" encoding="UTF-8"?>
<ejb-jar-bnd xmlns="http://websphere.ibm.com/xml/ns/javaee"
 xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://websphere.ibm.com/xml/ns/javaee
 http://websphere.ibm.com/xml/ns/javaee/ibm-ejb-jar-bnd_1_0.xsd" version="1.0">
 <session name="FacadeBean" simple-binding-name="ejb/session/FacadeBean"/>
</ejb-jar-bnd>
```

This binding file content assumes that the session bean whose ejb-name is "FacadeBean" implements a single business interface, and thus the simple-binding-name attribute can be used as an alternative to the <interface> subelement. In this case, the FacadeBean implements a single remote business interface, bound at ejb/session/FacadeBean in the server root JNDI context of the application server where the FacadeBean resides.

### Code snippet (calling bean)

```
@EJB(name="ejb/FacadeRemoteRef")
FacadeRemote remoteRef;
try {
     output = remoteRef.orderStatus(input);
}
catch (Exception e) {
     // Handle exception, etc.
}
```

This code snippet performs an EJB resource injection into the instance variable named "remoteRef", which is of type FacadeRemote. The injection overrides the "name" parameter, setting the resulting ejb-ref reference name to ejb/FacadeRemoteRef. The code invokes a business method on the injected reference.

### ibm-ejb-jar-bnd.xml (calling bean)

```
<?xml version="1.0" encoding="UTF-8"?>
<ejb-jar-bnd xmlns="http://websphere.ibm.com/xml/ns/javaee"
 xmlns:xsi="
 http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://websphere.ibm.com/xml/ns/javaee
 http://websphere.ibm.com/xml/ns/javaee/ibm-ejb-jar-bnd_1_0.xsd" version="1.0">
 <session name="CallingBean">
  <ejb-ref name="ejb/FacadeRemoteRef"
   binding-name="cell/nodes/S35NLA1/servers/S35serverA1/ejb/session/FacadeBean"/>
 </session>
</ejb-bnd-jar>
```

Finally, this binding file resolves the EJB reference with an ejb-ref name of ejb/FacadeRemoteRef to point to the classic globally scoped JNDI name of cell/nodes/S35NLA1/servers/S35serverA1/ejb/session/FacadeBean. This classic globally scoped JNDI name represents an interface bound at ejb/session/FacadeBean under the server root context of the server named "S35serverA1" on the node

named "S35NLA1" within the WebSphere Application Server cell of the calling bean. To point to a location within a different WebSphere Application Server cell, a CORBAName-style name can be used instead of a standard JNDI name.

Instructions on how to modify the ibm-ejb-jar-bnd.xml file can be found in the topic, Ways to update application files.

## The relationship between injections and references

There is a one-to-one correspondence between injection directives and reference declarations - every injection implicitly defines a reference of some type, and conversely, every reference can optionally also define an injection. You can think of an injection annotation as being the mechanism to define references through annotations rather than defining them in the XML deployment descriptor.

By default, an injection defines a reference with a name formed from the package-qualified class name of the component performing the injection, a forward slash (/), then the name of the variable or property being injected into. For example, an injection performed in the class com.ejbs.AccountService, into a variable or property named "depositService", results in a reference named java:comp/env/com.ejbs.AccountService/depositService. However, specifying the optional "name" parameter on the injection directive overrides this default name and causes the reference to be named according to the value of the "name" parameter.

Knowing this rule, it is easy to see how a bindings file can be used not only to resolve targets for references declared in an XML deployment descriptor, but also to resolve targets for references implicitly declared by an annotation injection directive. Simply use the value of the "name" parameter on the injection annotation, or the default reference name from the class name and variable/property name if no "name" parameter is specified, as if it were the name of the reference declared in an XML deployment descriptor.

## Default resolution of EJB references and EJB injections: The EJBLink and AutoLink features

The *EJBLink* and *AutoLink* features are two different mechanisms that resolve references to EJB components that are packaged in the same application and application server process as the referring component. Both EJBLink and AutoLink remove the need to explicitly resolve the EJB reference with binding information. The EJBLink feature is defined by the EJB specification, while the AutoLink feature is a WebSphere Application Server extension.

The EJBLink and AutoLink features use different search criteria to locate the targetted bean component. EJBLink searches for the targetted bean component using the explicitly specified bean name. AutoLink searches for the targetted bean component using the interface that the bean implements. If no explicit bindings are provided, but a bean name is provided, then the EJBLink feature is used. If no explicit bindings are provided, and no bean name is provided, then the AutoLink feature is used. The EJBLink and AutoLink features are never used together as part of the same search process.

Except for the search criteria, the EJBLink and AutoLink features are similar. Both features search a specific module first, and then if needed fall back to searching the other modules in the same application and application server process. Both features require that the search criteria resolve to exactly one bean component, and consider it an error condition when the search criteria resolves to multiple bean components. An error condition exists because the application server does not know that which of the multiple bean components must be used. In this case, the exception com.ibm.websphere.ejbcontainer.AmbiguousEJBReferenceException occurs. This exception is thrown at run time when the referencing component attempts to find the targetted bean component.

The EJBLink feature supports three different formats.

- Specify only the name of the bean component. For example, MyBean.

- Specify the name of the physical module file, including the extension, that contains the targeted bean component, followed by the # character, followed by the name of the bean component. For example, myModule.jar#MyBean
- Specify the logical name of the module that contains the targeted bean component, the slash character (/), followed by the name of the bean component. For example, MyModule/MyBean.

You can optionally specify the logical name of the module using the module-name element in the EJB deployment descriptor for an ejb-jar module, or you can use the module-name element in the web deployment descriptor file for a WAR module that contains EJB content. For a WAR module that contains EJB content, the module-name element specified in the EJB deployment descriptor is ignored, and the module-name element specified in the web deployment descriptor is processed. When no module-name value is specified in the deployment descriptor, a default logical name is assigned to the module. The default logical module name is the base name of the module file, minus the extension. For example, the module file, MyModule.jar, has the default logical module name MyModule.

Specifying the name of the physical module file is still supported even when the module has a logical name. Specifying the logical name of the module is still supported even when no logical module name is configured in the deployment descriptor. In this case, the base name of the module is used as the logical name of the module.

The embeddable EJB container supports all EJBLink formats. To support the physical module file format, the embeddable EJB container does not allow you to start multiple modules with the same base name.

AutoLink is a value-add feature of WebSphere Application Server that eliminates the need to explicitly resolve EJB reference targets in certain usage scenarios. In WebSphere Application Server V8, AutoLink is implemented within the boundaries of each WebSphere Application Server process. The AutoLink algorithm works as follows.

When the EJB container in the product encounters an EJB reference within a given EJB module, it first checks to see if you have explicitly resolved the target of that reference through inclusion of an entry in the binding file of the module. If it finds no explicit resolution of the target in the binding file, the container searches within the referring module for an enterprise bean that implements the interface type or no-interface view you have defined within the reference.

If it finds *exactly one* enterprise bean within the module that implements the interface or no-interface view, it uses that enterprise bean as the target for the EJB reference. If the container cannot locate an enterprise bean of that type within the module, it expands the search scope to the application that the module is part of, and searches other modules within that application that are assigned to the same application server as the referring module. Again, if the container finds *exactly one* enterprise bean that implements the target interface or no-interface view, within the other modules of the application assigned to the same server as the referring module, it uses that enterprise bean as the reference target.

The scope of AutoLink is limited to the application in which the EJB reference appears, and to the application server on which the referring module is assigned. References to enterprise beans in a different application, enterprise beans in a module assigned to a different application server, or to enterprise beans residing in a module that has been assigned to a WebSphere Application Server cluster, must be explicitly resolved using reference target bindings in the `ibm-ejb-jar-bnd.xml` file of the EJB module, or the `ibm-web-bnd.xmi` file of the web module.

It is important to note that AutoLink is only supported for EJB references, not other types of references although it is supported from the EJB container, the web container, and the application client container. Also, because the scope of the AutoLink function is limited to the server that the referring module is assigned to, or in the case of the Java EE client container, to the server that the client container is configured as its JNDI bootstrap server, it is useful mainly in development environments and other single-server usage scenarios. Even with these present limitations, it can be a significant value during the development experience by removing the need to explicitly resolve EJB references.

## Resolution of EJB and resource references and injections: The lookup feature

The lookup feature is defined by the EJB 3.1 specification as a mechanism that resolves references to EJBs or resources, by an explicit JNDI name. You can specify the lookup attribute on the javax.ejb.EJB annotation or on the javax.annotation.Resource annotation. The corresponding XML attribute in the `ejb-jar.xml` file is <lookup-name>, on one of the following elements: <ejb-ref>, <ejb-local-ref>, <env-entry>, <resource-ref>, <resource-env-ref>, or <message-destination-ref>. lookup or <lookup-name> is a JNDI name relative to the java:comp/env naming context.

On an EJB reference, lookup or <lookup-name> must not be specified with beanName or with <ejb-link>. The administrative console displays lookup-name and ejb-link as read-only. However, if a JNDI name is specified in the application installation step "Map EJB references to beans", it overrides the lookup-name or ejb-link value.

## Overriding environment entries defined in applications

Applications might define environment entries with values that are suitable for unit testing, but not for integration testing or production use. If you want to override an environment entry value, you can add the following element to the corresponding binding file:

```
<env-entry name="name" value="value"/>
```

where *name* is the env-entry name as it is defined in the application and *value* is the value assigned to the env-entry represented in string format. The string for *value* is parsed according to the type of the environment entry as if the value had been specified in the deployment descriptor using env-entry-value. For example,

```
<env-entry name="java:module/env/taxYear" value="2010"/>
```

associates the env-entry named "java:module/env/taxYear" with a value of "2010".

Alternatively, you can configure an env-entry as a reference to another object accessible through JNDI. The object returned from the JNDI lookup is used as the env-entry value. The element for that option has the following form:

```
<env-entry name="name" binding-name="lookupName"/>
```

where *name* is the env-entry name as it is defined in the application and *lookupName* is a JNDI name that resolves when applied to a lookup on the default initial context. For example,

```
<env-entry name="java:module/env/taxYear" binding-name="cell/persistent/MyApp/MyModule/taxYear"/>
```

associates the env-entry named "java:module/env/taxYear" with a value returned from a default initial context lookup operation on "cell/persistent/MyApp/MyModule/taxYear". You are responsible for creating the JNDI object binding. The class of the bound object must be assignable to the object type of the associated env-entry.

Environment entries can be defined at the application level and in EJB, web, and client modules. Those levels correspond to the binding files application-bnd.xml, ejb-jar-bnd.xml, web-app-bnd.xml, and application-client-bnd.xml.

## Overriding data source definitions

With Java EE 6, you can develop applications that define data sources using the @DataSourceDefinition annotation or <data-source> deployment descriptor entry.

Your applications should look up resource references as opposed to looking up data source definitions directly. If you are installing an existing application that contains direct lookups to a data source definition,

and you want it to use another data source definition, you can override the data source definition with a binding that resolves to a managed resource that you create. Create the binding by adding the following element to your binding file:

```
<data-source name="name" binding-name="lookupName"/>
```

where *name* is the env-entry name as it is defined in the application and *lookupName* is a JNDI name that resolves when applied to a lookup on the default initial context. For example,

```
<data-source name="java:module/env/myDS" binding-name="jdbc/DB2DS"/>
```

causes lookups on "java:module/env/myDS" to resolve to the data source bound with the name, "jdbc/DB2DS", relative to the default initial context. The data source bound under jdbc/DB2DS can be created, for example, through the administrative console.

Data sources can be defined at the application level and in EJB, web, and client modules. Those levels correspond to the binding files application-bnd.xml, ejb-jar-bnd.xml, web-app-bnd.xml, and application-client-bnd.xml.

## Naming considerations in clustered and cross-server environments

The classic global JNDI naming conventions in the previous sections apply in non-clustered environments and when the lookup target is within the same cluster as the source of the lookup. When a lookup is performed from outside a cluster on a binding that is within a given cluster, the lookup string must be qualified to indicate the name of the cluster in which the target resides, according to the following convention:

```
cell/clusters/<cluster-name>/<name-binding-location>
```

For example, given an EJB interface binding location within the application server root context:

```
ejb/Department549/AccountProcessors/CheckingAccountReconciler
```

If the EJB implementing this interface is assigned to an application server that is a member of a cluster named Cluster47, the lookup string external to that cluster is as follows:

```
cell/clusters/Cluster47/ejb/Department549/AccountProcessors/CheckingAccountReconciler
```

When a lookup is performed across application server processes, the lookup string must be qualified to indicate the name of the node and server in which the target resides, according to the following convention:

```
cell/nodes/<node-name>/servers/<server-name>/<name binding location>
```

Again, given an EJB interface binding location within the application server root context:

```
ejb/Department549/AccountProcessors/CheckingAccountReconciler
```

If the enterprise bean that is implementing this interface is assigned to an application server named Server47A1 that is located on a node named S47NLA1, the cross-server lookup string is as follows:

```
cell/nodes/S47NLA1/servers/Server47A1/ejb/Department549/AccountProcessors/CheckingAccountReconciler
```

## User-defined EJB extension settings

For cases where you want to specify values for WebSphere Application Server EJB Extension settings, you can use an *EJB module extension file* to assign these settings to specific EJB types within that module. You specify extension settings information for EJB 3.x modules by placing one, or both, of two files into the META-INF directory for the EJB JAR file, depending on the type of extension being defined. The names of the two files are `ibm-ejb-jar-ext.xml` and `ibm-ejb-jar-ext-pme.xml`.

**Note:** The suffix on these files are XM**L**, not XM**I** as in prior versions of WebSphere Application Server.

The ibm-ejb-jar-ext.xml and ibm-ejb-jar-ext-pme.xml files are used for **EJB 3.x** modules running in WebSphere Application Server, whereas the `ibm-ejb-jar-ext.xmi` and `ibm-ejb-jar-ext-pme.xmi` files are used for **pre-3.0 EJB** modules. WebSphere Application Server Version 8.0 uses a new XML-based extension file format instead of the previous `.xmi` file format for the following reasons:

1. Bindings and extensions declared in the xmi file format depend on the presence of a corresponding ejb-jar.xml deployment descriptor file, explicitly referring to unique ID numbers attached to elements in that file. This system is no longer viable for EJB 3.0 and later modules, where it is no longer a requirement for the module to contain an ejb-jar.xml deployment descriptor.
2. The xmi file format was designed to be machine-edited only by WebSphere development tools and system management functions; it was effectively part of WebSphere's internal implementation and the structure of the file was never documented externally. This made it impossible for developers to manually create or edit binding or extension files, or create them as part of a WebSphere independent build process, in a supported manner.
3. Rather than referring to encoded ID numbers in ejb-jar.xml, the XML-based extension file format refers to EJB components by their EJB name. Each EJB component in a module is guaranteed to have a unique EJB name, either by default or through explicit assignment by the developer, so this provides an unambiguous way to target bindings and extensions.
4. The new binding and extension file formats are XML-based, and XML Schema Definition (xsd) files are provided to externally document their structure. These .xsd files might be consumed by many common XML file editors to assist in syntactic verification and code completion functions. As a result, it is now possible for developers to produce and edit these binding and extension files independently of WebSphere Application Server infrastructure, using a generic XML editor or scripting system of their choice.

### Extensions defined in META-INF/ibm-ejb-jar-ext.xml

The following tables list extension elements and attributes that must be placed in the `META-INF/ibm-ejb-jar-ext.xml` file. The next section lists elements and attributes that appear in a separate file, `META-INF/ibm-ejb-jar-ext-pme.xml`.

*Table 88. Elements and attributes of the `META-INF/ibm-ejb-jar-ext.xml` file. Elements and attributes of the `META-INF/ibm-ejb-jar-ext.xml` file*

| Element or Attribute | Description | Example | Usage notes |
|---|---|---|---|
| <session> | Declares a group of extension settings for a session bean. | `<session name="AccountServiceBean"/>` | Requires *name* attribute. In order to have any effect, also include at least one extension setting definition subelement. |
| <message-driven> | Declares a group of extension settings for a message-driven bean. | `<message-driven name="EventProcessorBean"/>` | Requires *name* attribute. In order to have any effect, also include at least one extension setting definition subelement. |

*Table 89. Elements and attributes of the `META-INF/ibm-ejb-jar-ext.xml` file. Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file*

| Element or Attribute | Description | Example | Usage notes |
|---|---|---|---|
| <time-out> | Subelement to the <session> element that optionally declares the number of seconds between method invocations after which a *stateful* session bean might no longer be available. | `<session`<br>` name="ShoppingCartBean">`<br>` <time-out value="600"/>`<br>`</session>` | Requires *value* attribute, a positive integer. **Only applicable to stateful session beans; must not be used on stateless beans.**<br><br>Attribute default: 300 (10 minutes) |

*Table 89. Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file (continued). Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file*

| Element or Attribute | Description | Example | Usage notes |
|---|---|---|---|
| <bean-cache> | Subelement of <session> element used to declare bean activation/passivation settings for stateful session beans. | <session<br>name="ShoppingCartBean><br><bean-cache<br>activation-policy="TRANSACTION"/><br></session> | To have any effect, also include the activation-policy attribute. |
| activation-policy | Attribute of <bean-cache> element that declares the conditions under which the bean instance might be activated and passivated. Applicable to stateful session beans. Allowable values and their meanings are:<br>• **TRANSACTION:** Indicates that the bean activates at the start of a transaction and passivates (and is removed from the active EJB instance cache) at the end of the transaction.<br>• **ONCE:** Indicates that the bean activates when it is first accessed in the server process, and passivates (and is removed from the active EJB instance cache) at the discretion of the container, for example, when the cache becomes full.<br>• **ACTIVITY_SESSION:** Indicates that the bean activates and passivates as follows: 1) On an ActivitySession boundary, if an ActivitySession context is present on activation, 2) On a transaction boundary, if a transaction context (but no ActivitySession context) is present on activation, or otherwise, 3) on an invocation boundary. | <session<br>name="ShoppingCartBean><br><bean-cache<br>activation-policy="ONCE"/><br></session> | Attribute default: ONCE for stateful session beans. |

*Table 90. Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file. Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file*

| Element or Attribute | Description | Example | Usage notes |
|---|---|---|---|
| <global-transaction> | Subelement to the <session> and <message-driven> elements that can be used to declare the transaction timeout (in seconds) to be used on transactions started by this specific EJB type (overriding the server setting for global transaction timeout) and also might declare whether this EJB type propagates global transaction context received through web service atomic transactions, across the heterogeneous web service environment. | <session<br>name="AccountServiceBean"<br><global-transaction<br>transaction-timeout="180"<br>send-wsat-context="FALSE"/><br></session> | Requires at least one of transaction-timeout or send-wsat-context attributes.<br><br>Attribute default: Server transaction timeout setting for transaction-timeout; FALSE for send-wsat-context |

*Table 90. Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file (continued). Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file*

| Element or Attribute | Description | Example | Usage notes |
|---|---|---|---|
| <local-transaction> | Subelement to the <session> and <message-driven> elements that can be used to declare settings related to local transactions. Supported attributes are boundary, resolver, and unresolved-action; these attributes configure, for the component, the behavior of the local transaction containment (LTC) environment of the container that the container establishes whenever a global transaction is not present. The meaning of each attribute is as follows:<br><br>**Boundary**<br><br>This setting specifies the containment boundary at which all contained resource manager local transactions (RMLTs) must be completed. Possible values are:<br>• **BEAN_METHOD:** This is the default value. If you select this option, RMLTs must be resolved within the same bean method in which they were started.<br>• **ACTIVITY_SESSION:** RMLTs must be resolved within the scope of any ActivitySession in which they were started or, if no ActivitySession context is present, within the same bean method in which they were started.<br><br>**Resolver**<br><br>This setting specifies the component responsible for initiating and ending RMLTs. Possible values are:<br>• **APPLICATION:** This is the default value. The application is responsible for starting RMLTs and for completing them within the local transaction containment (LTC) boundary. Any RMLTs that are not completed by the end of the LTC boundary are cleaned up by the container according to the value of the Unresolved action attribute.<br>• **CONTAINER_AT_BOUNDARY:** The container is responsible for starting RMLTs and for completing them within the LTC boundary. The container begins an RMLT when a connection is first used within the LTC scope, and completes it automatically at the end of the LTC scope. If Boundary is set to ActivitySession, the RMLTs are enlisted as ActivitySession resources and directed to complete by the ActivitySession. If Boundary is set to BeanMethod, the RMLTs are committed at the end of the method by the container.<br><br>**Unresolved Action**<br><br>This setting specifies the direction that the container requests RMLTs to take, if those transactions are unresolved at the end of the LTC boundary scope and the Resolver is set to Application. Possible values are:<br>• **ROLLBACK:** This is the default value. At end of the LTC boundary scope, the container instructs all unresolved RMLTs to roll back.<br>• **COMMIT:** At the end of the LTC boundary scope, the container instructs all unresolved RMLTs to commit. The container instructs the RMLTs to commit only in the absence of an unhandled exception. If the application method that is running in the local transaction context ends with an exception, any unresolved RMLTs are rolled back by the container. This is the same behavior as for global transactions. | `<session`<br>` name>="AccountServiceBean">`<br>` <local-transaction`<br>`  boundary="BEAN_METHOD"`<br>`  resolver="APPLICATION"`<br>`  unresolved-action="ROLLBACK"/>`<br>`</session>` | Requires at least one of boundary, resolver, or unresolved-action attributes.<br><br>Attribute default:<br>`boundary="BEAN_METHOD";`<br>`resolver="APPLICATION";`<br>`unresolved-action=`<br>`"ROLLBACK"` |

*Table 91. Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file. Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file*

| Element or Attribute | Description | Example | Usage notes |
|---|---|---|---|
| <method> | Sub-element to the <method-session-attribute> and <run-as-mode> elements that is used to specify the method name, method signature, or method types to which a given setting might apply. Supported attributes are type, name, and params. The meaning of each attribute is as follows:<br><br>**type**<br>• **UNSPECIFIED:** The setting applies to all methods matching the name and params attributes, regardless of interface type.<br>• **REMOTE:** The setting applies to remote business interface and remote component interface methods matching the name and params attributes.<br>• **LOCAL:** The setting applies to local business interface, local component interface methods, and no-interface views that match the name attribute, params attribute, or both.<br>• **HOME:** The setting applies to remote home interface methods matching the name and params attributes matching the name and params attributes.<br>• **LOCAL_HOME:** The setting applies to local home interface methods matching the name and params attributes.<br>• **SERVICE_ENDPOINT**: The setting applies to methods on the JAX-RPC service endpoint interface matching the name and params attributes.<br><br>**name**<br><br>The name of the method to which the setting is applied, or an asterisk (*) if the setting is to be applied to all methods regardless of name.<br><br>**params**<br><br>The parameter signature of the method to which the setting is applied. This can be used to uniquely qualify a particular method in cases where more than a single method uses the same name. The parameter signature is a comma-separated list of Java types. Primitive types are specified using their name only; non-primitive types are specified using their fully qualified class or interface name including any Java package, and arrays of Java types are specified by the type of the array element followed by one or more pair of square brackets (for example int[][]). | `<session`<br>` /name="AccountServiceBean">`<br>` <method-session-attribute`<br>`  type="REQUIRES_NEW">`<br>` <method`<br>`  type="LOCAL"`<br>`  name="debitAccount"`<br>`  params="java.lang.String[], int,`<br>`  com.xyz.CustomerInfo"/>`<br>` </method-session-attribute;>`<br>`</session>` | |
| <run-as-mode> | Sub-element to the <session> and <message-driven> elements that can be used to declare the security identity that a given EJB method might have while the method is being executed. The identity can be set to use the identity of the caller (mode = CALLER_IDENTITY), the identity of the EJB server (mode = SERVER_IDENTITY), or the identity of a specific security role (mode = SPECIFIED_IDENTITY). | `<session`<br>` name="AccountServiceBean">`<br>` <run-as-mode`<br>`  mode="SPECIFIED_IDENTITY">`<br>` <specified-identity`<br>`  role="admin"/>`<br>` <method type="UNSPECIFIED"`<br>`  name="testRunAsRole"/>`<br>` </run-as-mode>`<br>`</session>` | Requires mode attribute and <method> subelement. If the mode is SPECIFIED_IDENTITY, the <specified-identity subelement is also required. |
| <start-at-app-start> | Subelement to the <session> and <message-driven> elements that can be used to inform the EJB container that specified EJB type might be initialized at the time the application is first started, rather than the time the EJB type is first used by the application. | `<session`<br>` name="AccountServiceBean">`<br>` <start-at-app-startvalue="TRUE"/>`<br>`</session>` | Requires value attribute.<br><br>Attribute default: FALSE (initialize EJB type when EJB is first used by application) for beans other than message-driven beans. Always TRUE for message-driven beans. |

*Table 91. Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file (continued). Elements and attributes of the META-INF/ibm-ejb-jar-ext.xml file*

| Element or Attribute | Description | Example | Usage notes |
|---|---|---|---|
| <resource-ref> | Subelement to the <session> and <message-driven> elements, that might be used to declare additional settings on a Java EE resource reference, such as isolation level to be used on transactions driven through the connection referred to by the reference. Allowable attributes include *isolation-level*. The meaning of each attribute is as follows:<br><br>**isolation-level**<br>• **TRANSACTION_REPEATABLE_READ:** This isolation level prohibits dirty reads and nonrepeatable reads, but it allows phantom reads.<br>• **TRANSACTION_READ_COMMITTED:** This isolation level prohibits dirty reads, but allows nonrepeatable reads and phantom reads.<br>• **TRANSACTION_READ_UNCOMMITTED:** This isolation level allows reading uncommitted changes (data changed by a different transaction that is still in progress). It also allows dirty reads, nonrepeatable reads, and phantom reads.<br>• **TRANSACTION_SERIALIZABLE:** This isolation level prohibits the following types of reads: 1) Dirty reads, in which a transaction reads a database row containing uncommitted changes from a second transaction, 2) Nonrepeatable reads, in which one transaction reads a row, a second transaction changes the same row, and the first transaction rereads the row and gets a different value, and 3) Phantom reads, in which one transaction reads all rows that satisfy an SQL WHERE condition, a second transaction inserts a row that also satisfies the WHERE condition, and the first transaction applies the same WHERE condition and gets the row inserted by the second transaction.<br>• **TRANSACTION_NONE:** This isolation level indicates that transactions are not supported on this type of resource. | `<session`<br>` name="AccountServiceBean">`<br>` <resource-ref`<br>`  name="jdbc/Default"`<br>`  isolation-level="TRANSACTION_NONE">`<br>`</session>` | Requires name attribute. To have any effect, also include the isolation-level attribute. |

## Extensions defined in META-INF/ibm-ejb-jar-ext-pme.xml file

The following tables list extension elements and attributes that must be placed in the META-INF/ibm-ejb-jar-ext-pme.xml file.

*Table 92. Extensions defined in META-INF/ibm-ejb-jar-ext-pme.xml. Extensions defined in META-INF/ibm-ejb-jar-ext-pme.xml*

| Element or Attribute | Description | Example | Usage notes |
|---|---|---|---|
| <internationalization> | Element that might be used to declare the locale that might be used by the EJB type (locale of the caller or locale of the server). | <internationalization><br><application><br><ejb name="S01"/><br><ejb name="S02"/><br></application><br><run-as-caller><br><method type="LOCAL" name="getFoo" params="int"><br><ejb name="C01"/><br></method><br></run-as-caller><br><run-as-server><br><method type="LOCAL" name="getBar" params="int"><br><ejb name="C02"/><br></method><br></run-as-server><br><run-as-specified name="North American English"><br><locale lang="en" country="US" variant="foo"/><br><locale lang="en" country="CA" variant="bar" /><br><time-zone name="GMT"/><br><method type="LOCAL" name="getFoo" params="int"><br><ejb name="C03"/><br></method><br></run-as-specified><br><run-as-specified name="North American French"><br><locale lang="fr" country="US" variant="foo"/><br><locale lang="fr" country="US" variant="bar" /><br><time-zone name="GMT" /><br><method type="LOCAL" name="getBar" params="int"><br><ejb name="C04"/><br></method><br></run-as-specified><br></internationalization> | For information about this extension, see Container internationalization attributes: WebSphere Application Server.<br><br>Due to the complexity of this function, you might want to use a tool designed for WebSphere Application Server such as Rational Application Developer to produce the wanted extension file stanzas, then modify the XML file as wanted. |
| <activity-sessions> | Element that optionally declares the type of activity session management to be used on a designated session bean (BEAN or CONTAINER) and for container-managed activity sessions, the type of activity session behavior to be provided by the container. | <activity-sessions><br><container-activity-session<br>name="Foo" type="NOT_SUPPORTED"><br><methodtype="HOME" name="findByPrimaryKey"<br>params="int"><br><ejb name="C01"/><br></method><br></container-activity-session><br><./activity-sessions> | For information about this extension, see Setting EJB module ActivitySession deployment attributes.<br><br>Due to the complexity of this function, you might want to use a tool designed for WebSphere Application Server such as Rational Application Developer |

## Legacy (XMI) bindings

Existing modules and applications can continue to use the legacy binding support provided in the product, therefore, the existing tools and wizards can be used to specify binding and extension information for applications and modules. Use of the legacy support is limited to EAR files and modules using J2EE 1.4-style XML deployment descriptors.

EJB modules that use a version 3.x XML deployment descriptor schema or do not have an XML deployment descriptor file must use either defaulted bindings and AutoLink, or user-specified XML binding files.

It is required that CMP entity beans always be packaged in a module with a 2.1 XML deployment descriptor schema version so that existing tools can be used to provide mappings, bindings, and extension support.

### User-specified XML bindings

The default bindings for each interface and AutoLink reference resolution for each reference can be overridden by specifying bindings for the EJB module by creating a `META-INF/ibm-ejb-jar-bnd.xml` file.

The schema files that describe the format are located in the <WAS_HOME>/properties/schemas directory. This form of bindings specification can only be used for modules containing either no XML deployment descriptor or an EJB 3.x deployment descriptor.

**Note:** It is not required to specify all bindings. Any binding name or reference that is not defined uses the default bindings and AutoLink support.

Bindings can be specified for the following beans:

- Session beans using the <session> element.
- Message Driven beans using the <message-driven> element

The only attributes and subelements supported for the <session> element are:

- id attribute
- name attribute
- simple-binding-name attribute
- component-id attribute
- ejb-ref element
- resource-ref element and its attributes
- resource-env-ref element and its attributes
- message-destination-ref element and its attributes
- env-entry element
- data-source element

The only attributes and sub elements supported for the <message-driven> element are:

- id attribute
- name attribute
- jca-adapter attribute
- ejb-ref element and its attributes
- resource-ref element and its attributes
- resource-env-ref element and its attributes
- message-destination-ref element and its attributes
- env-entry element
- data-source element

## EJB 3.x module packaging overview

This topic describes application packaging when you use Enterprise JavaBeans (EJB) 3.x beans.

Packaging applications that use EJB 3.x beans is similar to the assembly requirements for Java Platform, Enterprise Edition (Java EE) 1.4 applications: components are packaged into modules, and modules are packaged into application enterprise archive (EAR) files. The components and modules both have describing metadata provided in an Extensible Markup Language (XML) deployment descriptor. The EJB 3.x specifications support an additional method to describing metadata and for packaging persistence units.

The EAR file is a package file format similar to a .zip or .tar file format. The EAR file can be visualized as a collection of logical directories and files that are packaged together into a simple file. Each EAR file includes one or more Java EE module files, which can include the following modules:

- Java application archive (JAR) files for EJB modules. Java EE application client modules and utility class modules.
- Web application archive (WAR) files for web modules, or EJB content. The WAR file must be version 2.5 or higher to contain EJB content.
- Other technology-specific modules such as resource application archive (RAR) files and other types of modules.

## EJB modules without deployment descriptors

You can package EJB modules without a deployment descriptor if you are using EJB 3.x beans. To do this, you must create a JAR file or WAR file with metadata in an annotation which is located in the EJB component. EJB 3.x beans do not need an entry in the `ejb-jar.xml` file for metadata that you have defined through annotations.

With EJB 3.0, the default was to scan annotations during the installation of an EJB 3.0 module. For WebSphere Application Server, Version 8.0, the default is not to scan pre-Java EE 5 modules during the application installation or at server startup.

To preserve backward compatibility with both the Feature Pack for EJB 3.0 and the Feature Pack for Web Services, you have a choice whether to scan legacy web modules for additional metadata. A server level switch is defined for each feature pack scan behavior. If the default is not appropriate, the switch must be set on each server and administrative server that requires a change in the default. The switches are server custom properties com.ibm.websphere.webservices.UseWSFEP61ScanPolicy={true|false} and com.ibm.websphere.ejb.UseEJB61FEPScanPolicy={true|false}. To define these properties in the administrative console click **Application servers** > ***server name*** > **Process definition** > **Java Virtual Machine** > **Custom properties**.

## EJB modules with deployment descriptors

You can continue to use EJB modules with deployment descriptors. Modules with deployment descriptors can support any EJB specification version level, including EJB 3.x, but generally these descriptors should reflect the implementation requirements of the components in the module.

An EJB module can have an EJB 3.x, 2.x, or 1.x deployment descriptor.

For EJB 2.x or 1.x deployment descriptors, it is assumed that the deployment descriptor contains the full metadata for the module, and no additional scanning of annotation metadata occurs.

The EJB container annotation scanning is performed on EJB modules that either have no deployment descriptor or have an `ejb-jar.xml` deployment descriptor at the EJB 3.0 schema level with the metadata-complete XML attribute set to false or omitted. See the Annotation scanning behavior section for the complete set of rules used by the server to determine if annotation scanning is performed.

**Note:** You cannot scan for component annotation metadata contained within shared libraries defined using the WebSphere Application Server system management shared library feature. However, content defined as a BLA Asset is scanned for annotation data.

## Annotation scanning behavior

The server can inspect the class files in the module for annotation content. The server searches for annotation content that might define a component, a reference to a resource, or a particular behavior. For example, annotations might be used to define an EJB component, or to declare a reference to a data source that must be used by an EJB component, or to declare the transactional or security attributes that are associated with an EJB method. This inspection process is referred to as annotation scanning. If the class files in the module contain annotations that must be respected by the server, then the server must be configured so that annotation scanning occurs. If the class files in the module do not contain annotations, then for performance reasons you can configure the server so that annotation scanning does not occur.

The server uses the following criteria to determine whether it scans content for annotations:

- Whether the ejb-jar.xml deployment descriptor file exists
- Version of the ejb-jar.xml deployment descriptor, when it is exists
- Value of the metadata-complete setting in the ejb-jar.xml deployment descriptor, when it exists
- Version of the web.xml deployment descriptor, when the EJB content is packaged in a WAR module, and the ejb-jar.xml deployment descriptor does not exist
- Value of the metadata-complete setting in the web.xml deployment descriptor, when the EJB content is packaged in a WAR module, and the ejb-jar.xml deployment descriptor does not exist

The following tables indicate how the decision to scan, or not scan, annotations is made for EJB content that is packaged in an EJB JAR module or a WAR module.

*Table 93. Annotation scanning for EJB content packaged in an EJB JAR module. Annotation scanning for EJB content packaged in an EJB JAR module*

| ejb-jar.xml | metadata-complete value in ejb-jar.xml | Are annotations scanned? |
|---|---|---|
| Exists, with a version of 2.x or lower | NA | No |
| Exists, with a version of 3.x or higher | true | No |
| Exists, with a version of 3.x or higher | false (or omitted) | Yes |
| Does not exist | NA | Yes |

*Table 94. Annotation scanning for EJB content packaged in a WAR module. Annotation scanning for EJB content packaged in a WAR module*

| ejb-jar.xml file | metadata-complete value in ejb-jar.xml | web.xml file | metadata-complete value in web.xml | Are annotations scanned? |
|---|---|---|---|---|
| Exists, with a version of 3.x or higher | true | NA | NA | No |
| Exists, with a version of 3.x or higher | false (or omitted) | NA | NA | Yes |
| Exists, with a version of 2.x or lower | NA | NA | NA | No |
| Does not exist | NA | Exists, with a version of 2.5 or higher | true | No |
| Does not exist | NA | Exists, with a version of 2.5 or higher | false (or omitted) | Yes |
| Does not exist | NA | Exists, with a version of 2.4 or lower | NA | No |
| Does not exist | NA | Does not exist | NA | Yes |

**Note:**

It is important to understand the distinction between the metadata-complete attribute of the ejb-jar element of the `ejb-jar.xml` deployment descriptor, and the metadata-complete install setting that may be specified during the application or module installation process.

The metadata-complete attribute of the ejb-jar element of the `ejb-jar.xml` file is an XML attribute. It is used by the server to determine if classes must be scanned for annotation data, as just described by the rules in the Annotation Scanning For EJB Content tables.

In contrast, the metadata-complete setting that may be specified at install time is used by the server to help generate the `ejb-jar.xml` file. If no `ejb-jar.xml` file exists in the module, and the metadata-complete install setting is assigned a value of true, then the server scans for annotation content and uses that to generate an `ejb-jar.xml` file, and then sets the metadata-complete XML attribute in that file to a value of true.

## Persistence units

Persistence units, including the `persistence.xml` file and the classes associated with it, can be packaged in the module for which they are required. They can also be packaged in the separate utility JAR file that is packaged in the EAR file with its dependent module.

When a separate utility JAR file is packaged, it is necessary for the module that desires it to use the persistence units to declare a dependency on the utility JAR file using the typical MANIFEST. MF Class-Path: declarations. See the example scenario for this packaging method under the section in this topic called "Session facades used for persistence scenario"

**Note:** Packaging of persistence units contained within shared libraries defined using the WebSphere Application Server system management shared library feature is not supported at this time.

## Application packaging

You can mix EJB 2.x and earlier beans with EJB 3.x beans in the same application. However, EJB 3.x beans are not recognized in EJB 2.x or EJB 1.x modules.

In the case that the EAR file only contains the JAR and web application archive (WAR) files, and no `application.xml` file, the product provides a default J2EE 1.4 deployment descriptor that is based on the following defaults that are outlined in the Java EE specification:

- The application name is assumed to be the name of the EAR file, but with the EAR file extension removed.
- Files that are ending in .war are assumed to be web modules. The context root of the web module is the name of the file that is relative to the root of the application package, but with the WAR file extension removed.
- Files that are ending in .jar that are not in the /lib directory, and that contain either an `ejb-jar.xml` file or at least one class that defines a @Stateful, @Stateless, @Singleton, or @MessageDriven annotation, are assumed to be EJB modules.
- Other JAR files that are not in the /lib directory are not assumed to be EJB modules.

If the application archive file contains an `application.xml` descriptor, processing occurs according to the directives in that descriptor.

### AutoLink

AutoLink provides the ability to attempt to automatically resolve EJB references to components contained with an EAR file, without having to specify a JNDI binding name. This simplifies application deployment with large numbers of beans and references if they are unique and unambiguous.

**Restriction:** AutoLink should not be used for references to components deployed on a cluster.

## JPA packaging

It is recommend that persistence units be packaged in separate JAR files to make them more accessible and reusable. These can be tested outside the container, with or without actual database persistence occurring. Persistence units can be included in stand-alone applications or into EAR files as utility JAR files. Because of the variety of use cases and potential performance issues when scanning large quantities of classes, it is recommended that the persistence unit defines the classes of the persistence units.

## Session facades used for persistence scenario

A common pattern is to use session facades for persistence. Using session bean facades to drive JPA is supported. The EntityManager interface is not thread safe, therefore, servlets should never inject @PersistenceContext. Servlets must either use the facade pattern or use an EntityManagerFactory instance to create an EntityManager on each request.

It is recommended that JPA persistence units be defined in a separate JAR file, apart from the session bean facades. Not only is this a best practice that gives greater flexibility in sharing, it also avoids problems mixing JPA and non-JPA annotated classes.

Typically, a JAR file is created to hold the entity classes and the JPA `persistence.xml` definition and added to the EAR file as a utility JAR file. The EJB 3.x module adds a dependency on the JAR file by declaring it in the EJB 3.x module MANIFEST.MF. For example, if an EAR contains a `TradeApp.ear`, `TradeWeb.war`, `EJB3Trade.jar`, and `TradeInfo.jar` file, the `EJB3Trade.jar` file would have a MANIFEST.MF that looks like the following:

```
Manifest-Version: 1.0
Class-Path: TradeInfo.jar
```

The session facade in the `EJB3Trade.jar` file refers to JPA entity classes and persistence units in the `TradeInfo.jar` file. The web application defined in the `TradeWeb.war` file can do the same to work with the JPA entity objects as Data Transfer Objects flowing between the web and EJB container tiers.

## Cross-tier and cross version session bean reference scenario

There are several ways to define and use references to EJB 3.x session beans. For EJB 3.x session to session, the @EJB injection target can be used. For cross-tier, for example, web application to EJB 3.x session, or cross-version, for example, EJB 2.1 session to EJB 3.x session, an XML deployment descriptor reference can be used to define ejb-refs and ejb-local-refs. There are two variations of these, depending on whether an EJB 3.x business interface is referred to, or a pre-EJB 3.x component-style interface that also defines an EJBLocalHome is referred to. Web applications and client applications can also use the @EJB annotation if the component being referenced can be resolved using autolink.

For migration scenarios where session beans are being converted from EJB 2.1 beans to EJB 3.x beans, the pattern is typically to edit the Session bean class, replace the *implements SessionBean* with *implements the business interface*, remove *extends EJBLocalObject* from the local interface and non-business throws clauses, and add the @Stateful @Local @LocalHome(<localhome>.class) or similar annotations. Existing ejb-refs and ejb-local-refs are bound to the new implementation of the session bean.

**Note:** The default binding name does change.

The previous scenario uses an EJB 2.1-style client pattern with an EJB 3.x-style session bean implementation. For a more current client style, the client-side can be cleaned up to look up the session bean business interface directly, rather than going through a home interface. In this case, it is not necessary to define the @LocalHome(<localhome>.class) annotation. You can use a variant definition of

ejb-ref and ejb-local-ref to do this. Use a *null* value for the local-home element value and bind the ejb-local-ref to the session bean's ejblocal: binding rather than the home binding. For example:

```
<ejb-local-ref id="EJBLocalRef_1154112538064">
 <description>com.ibm.persistence.ejb3.order.facadecom.ibm.persistence.ejb3.order.facade</description>
 <ejb-ref-name>ejb/OrderEJB</ejb-ref-name>
 <ejb-ref-type>Session</ejb-ref-type>
 <local-home></local-home>
 <local>com.ibm.persistence.ejb3.order.facade.OrderProcessor</local>
</ejb-local-ref>
```

The client code also must be adjusted to do the appropriate casting for the object being looked up. In this case, the business interface instead of the home interface:

```
try {
 InitialContext ctx = new InitialContext();
 orderProcessor = (OrderProcessor)ctx.lookup("java:comp/env/ejb/OrderEJB");
}
catch(Exception e)  {
 e.printStackTrace(System.out);
 throw new ServletException(e);
}
```

# Assembling EJB 3.x modules

An enterprise bean is a managed Java component that can be combined with other resources to create Java Enterprise Edition (Java EE) applications.

## Before you begin

This topic assumes that you have created and unit tested an enterprise bean that you want to assemble in an enterprise application and deploy onto an application server.

## About this task

Assemble an EJB 3.x module to contain enterprise beans and related code artifacts. Group web components, client code, and resource adapter code in separate modules. After the EJB module is assembled, install it as a stand-alone application or combine it with other modules into an enterprise application.

To learn about how to assemble an EJB 3.x module with an assembly tool see the assembly tool information center.

Rational Application Developer can be extended with additional plug-ins to provide development support specifically for Java Persistence API (JPA).

See the Eclipse open source project, Dali, for a plug-in that provides this extension. See the related links in this topic for the Dali JPA tools website.

**Note:** Issues and problems using this plug-in need to resolved through the Eclipse open source community.

## What to do next

Deploy the EJB module.

# Assembling EJB modules

An enterprise bean is a Java component that can be combined with other resources to create Java Platform Enterprise Edition (Java EE) applications. This topic describes assembling Enterprise JavaBeans (EJB) modules based on the EJB specifications.

### Before you begin

This topic assumes that you have created and unit tested an enterprise bean file that you want to assemble in an enterprise application and deploy onto an application server.

### About this task

Assemble an EJB module to contain enterprise beans and related code artifacts. Group web components, client code, and resource adapter code in separate modules. After assembling an EJB module, you can install it as a stand-alone application or combine it with other modules into an enterprise application.

Use an assembly tool to assemble an EJB module in any of the following ways:
- Import an existing EJB module (EJB JAR file).
- Create a new EJB module.
- Copy code artifacts, such as entity beans, from one EJB module into a new EJB module.

For information on assembling EJB modules, refer to the online documentation or the information center for your assembly tool. The Rational Application Developer product provides supported assembly tools.

### Procedure
- Assemble an EJB 2.x module. See the topic Assembling EJB 2.x modules.
- Assemble an EJB 3.x module. See the topic Assembling EJB 3.x modules.

### What to do next

After you finish assembling your EJB module, you are ready to deploy your module.

## EJB modules

An Enterprise JavaBeans (EJB) module is used to assemble one or more enterprise beans into a single deployable unit. An EJB module is stored in a standard Java archive (JAR) file.

An EJB module contains the following:
- One or more deployable enterprise beans.
- A deployment descriptor, stored in an Extensible Markup Language (XML) file. This file declares the contents of the module, defines the structure and external dependencies of the beans in the module, and describes how the beans are to be used at run time.

  It is not necessary to use XML deployment descriptors in EJB 3.x modules, although XML descriptors are supported. Instead of deployment descriptors, you can use annotations to provide component metadata.

You can deploy an EJB module as a stand-alone application, or combine it with other EJB modules or with web modules to create a Java application. An EJB module is installed and run in an enterprise bean container.

If you want to package an EJB 3.x module with a deployment descriptor, there are several ways to do it. You can package an EJB 3.x module with an EJB 3.x style session and/or message-driven beans exclusively; with an EJB 2.1 style session and/or message-driven beans exclusively, or a combination of 2.1 and 3.x style beans. The XML deployment descriptor must be a Version 3.x deployment descriptor. It is required that 2.1 entity beans are packaged in modules with 2.1 deployment descriptors.

EJB modules that contain EJB 3.x beans must be at the EJB 3.x specification level when running on the product. To set the EJB module to support EJB 3.x beans, you can set the ejb-jar.xml deployment descriptor level to 3.0 or 3.1, or you can make sure that the module does not contain an ejb-jar.xml deployment descriptor. If the module level is EJB 2.1 or earlier, no EJB 3.x functions, including annotation scanning or resource injection is performed at run time.

For more information about packaging and deployment of EJB 3.x beans, see the topic EJB 3.x module packaging overview.

# EJB content in WAR modules

Use this topic to understand the packaging requirements of Enterprise JavaBeans (EJB) content in web application archive (WAR) modules.

## Supported EJB content

Except for explicitly stated restrictions, the EJB function that is supported for beans packaged inside EJB Java archive (JAR) modules is also supported for beans packaged inside WAR modules. A bean that is packaged inside a WAR module can have the same behavior as a bean that is packaged inside an EJB JAR module.

**Note:** All types of EJB 3.x beans are supported in WAR modules, and 2.x and 1.x session beans.

See the EJB 3.1 specification for complete details.

## Packaging mechanics

The rules for packaging EJB content in a WAR module are different from the rules for packaging EJB content in a JAR module.

The bean class files must be placed in one of two locations within the WAR module:

- Loosely in the `WEB-INF/classes` directory structure
- Within a JAR file that is placed in the `WEB-INF/lib` directory

For example, you might loosely place the bean class com.foo.MyBean in the WAR module at this location: `WEB-INF/classes/com/foo/MyBean.class`.

You might also place this bean class in the `myJar.jar` file, which is then placed in this location: `WEB-INF/lib/myJar.jar`.

A WAR module can have some bean code loosely placed in the `WEB-INF/classes` directory structure, and have other bean code inside JAR files in the `WEB-INF/lib` directory. It is also valid for a WAR module to have all the bean code in the `WEB-INF/classes` directory structure and nothing in the `WEB-INF/lib` directory, or all the bean code in JAR files in the `WEB-INF/lib` directory and nothing in `WEB-INF/classes`.

It is valid to have multiple JAR files in the `WEB-INF/lib` directory, all of which might contain bean code.

If the same bean class is loosely placed in the `WEB-INF/classes` directory structure and also placed in a JAR file in the `WEB-INF/lib` directory, then the instance of the class placed loosely in the `WEB-INF/classes` directory structure is loaded, and the instance placed in a JAR file in the `WEB-INF/lib` directory is ignored.

If the same bean class is placed in two different JAR files in the `WEB-INF/lib` directory, it is not known which instance of the class is loaded, and which instance is ignored. At run time, the server arbitrarily picks one class instance and loads it, and ignores the other class instance.

The EJB deployment descriptor files must be placed in the `WEB-INF` directory. This directory contains the `ejb-jar.xml` deployment descriptor, and any `ibm-ejb-jar-ext` and `ibm-ejb-jar-bnd` XML or XMI bindings and extensions files. EJB descriptor files that are located inside JAR files in the `WEB-INF/lib` directory are ignored. As with an EJB JAR module, there might be 0 or 1 instance of each EJB descriptor file. There cannot be multiple instances of any EJB descriptor file. This does not include the `persistence.xml file`, if one exists. Per the Java Persistence API specification, if a `persistence.xml` file is present, it must remain

in a META-INF directory located in either the WEB-INF/classes directory of the WAR module or in a JAR file in the WEB-INF/lib directory of the WAR module. For example:

- WEB-INF/classes/META-INF/persistence.xml
- WEB-INF/lib/MyEntity.jar

The MyEntity.jar contains META-INF/persistence.xml.

If an ejb-jar.xml file is located in a JAR file in the WEB-INF/lib directory, a warning message displays like the following:

```
IWAE0068W The EJB deployment descriptor META-INF/ejb-jar.xml in the library archive
 foo.jar file is ignored. The product does not process the META-INF/ejb-jar.xml deployment
 descriptor in library archives. Move the META-INF/ejb-jar.xml deployment descriptor from the
 library archive to the WEB-INF directory in the WAR module.
```

A WAR module must be version 2.5 or higher to contain EJB content. EJB content placed in a WAR module that is version 2.4 or lower is ignored.

**Note:** If a WAR module is version 2.5 or higher, the web metadata files containing bindings and extensions information must use the XML version of the files, not the XMI version.

## Technical differences for enterprise beans that are packaged in a WAR file

The following list contains key technical differences that exist between beans that are packaged in a WAR module and beans that are packaged in an EJB JAR module:

- Shared component namespace

  All components in a WAR module share a single component namespace. This means that each EJB component shares a single component namespace with all other EJB components in the WAR file, and any non-EJB components like servlets. In contrast, an EJB component that is packaged in an EJB JAR module has its own private component namespace, which is not shared with any other component.

  The shared component namespace has important impacts. First, one component (EJB or non-EJB) might declare a reference, and a different component might search the component namespace for that reference. Second, references declared by one component might conflict with references declared by another component. In contrast, an EJB packaged in an EJB JAR module cannot look up in the component namespace a reference declared by a different EJB or non-EJB component, and it is impossible for a reference declared by the EJB to conflict in the component namespace with a reference declared by any other component, even if the references have the same name.

  When using the shared namespace, it is valid for the same reference to be declared multiple times, as long as these reference declarations do not conflict with each other. If the reference declarations do not conflict, then the server behaves as if the reference had been declared exactly once.

  If reference declarations do conflict, then an error message is emitted, and the application fails to start. A warning message is emitted for each conflicted reference. The warning message indicates the name of the conflicted reference, and the multiple values assigned to that reference. After all the warning messages are emitted, an exception is thrown.
- Location of EJB descriptor files

  The ejb-jar.xml deployment descriptor file, and any other descriptor file, must be placed in the WEB-INF directory of the WAR. Any instance of an EJB descriptor file elsewhere in the WAR, including in the META-INF directory of a JAR file in the WEB-INF/lib directory, is ignored.
- Determining if annotations are scanned

  The rules for determining whether to scan for annotations are different for EJB JAR and WAR modules. See the topic, EJB 3.x module packaging overview, for the complete set of rules.
- Class loading and visibility

  The most common usage pattern for EJB classes that are packaged in a WAR module is local method invocations from web components packaged within the same module. However, these EJB classes can also be accessed by remote method invocations or by clients in other modules. In these cases, it is

important to understand the visibility rules of EJB classes that are packaged in a WAR module. Visibility rules are different when compared to EJB classes that are packaged in a JAR module.

In the case of remote EJB method invocations, there are no visibility differences introduced by packaging the EJB classes in a WAR module. The EJBs are bound into the global namespace and can be looked up from, or injected into, components in other modules. The remote client must make method invocations with an appropriate stub class. Stub class generation is described in this topic under the section, "Stub generation".

In the case of local EJB method invocations from components in other modules, there are visibility differences because the EJBs are packaged in a WAR module. These visibility differences occur because there are class loader implications that must be considered.

The content that is packaged in all EJB JAR modules for the entire application is loaded by a single application class loader instance.

In contrast, all content that is packaged in a WAR module is loaded on a class loader instance that is specific to that WAR module. The single application class loader instance that is used to load all the EJB JAR content, is the parent to each of the class loader instances that are used to load the WAR content.

The visibility of a class is affected by the class loader instance that loaded it. A class loader instance can see classes loaded by itself, or by a parent class loader. However, a class loader cannot see a class loaded on a class loader that is not itself, nor one of its parents.

As a result, classes loaded by a class loader specific to a WAR module can see classes in an EJB JAR module, but they cannot see classes in another WAR module. Classes in an EJB JAR module cannot see classes in any WAR module. For example, if there is EJB content packaged inside EJB JAR module `ejb3.jar`, and there is also EJB content packaged inside the `ejb1.jar` file and the `ejb2.jar` file, then:

- If the `ejb1.jar` file and the `ejb2.jar` file are installed as EJB JAR modules, then the content inside the `ejb1.jar` file, `ejb2.jar` file, and `ejb3.jar` file is all loaded on the same class loader instance, which is also used to load any other EJB JAR modules in the application. In this case, the classes in all three JAR files can see each other, because they are all loaded by the same class loader instance.
- If the `ejb1.jar` file and the `ejb2.jar` file are both packaged inside the `WEB-INF/lib` directory of a WAR file, the content inside the `ejb1.jar` file and the `ejb2.jar` file is loaded by a single class loader instance. However, this class loader is not the same one used to load the content for the `ejb3.jar` file and any other EJB JAR in the application. In this case, the classes in the `ejb1.jar` file and the `ejb2.jar` file can see each other and can also see the classes in the `ejb3.jar` file. The classes in the `ejb3.jar` file cannot see the classes in the `ejb1.jar` file or the `ejb2.jar` file.
- If the `ejb1.jar` file is packaged inside the `WEB-INF/lib` directory of the `firstWar.war` file, and the `ejb2.jar` file is packaged inside the `WEB-INF/lib` directory of the `secondWar.war` file, the content in the `ejb1.jar` file is loaded on one class loader instance, the content in the `ejb2.jar` file is loaded on a second class loader instance, and the content in the `ejb3.jar` file and all other EJB JAR in the application is loaded on a third class loader instance. In this case, the classes in the `ejb1.jar` file and the `ejb2.jar` file cannot see each other, but they can see the classes in the `ejb3.jar` file. The classes in the `ejb3.jar` file cannot see the classes in either the `ejb1.jar` file or the `ejb2.jar` file.

One strategy to avoid these class loader complications is to package the EJB interface classes in a shared library.

**Note:** Do not package the same class, both an EJB JAR module and a WAR module, in the same application. Packaging the same class in multiple locations within the same application might result in confusion regarding which instance of the class is loaded and used at run time. This distinction can matter if the two `.class` files represent different versions of the class. To avoid this scenario, package the `.class` file in only one location or change the package structure of the class so that the fully qualified name of the class packaged inside the WAR module is different from the fully qualified name of the class packaged inside the EJB JAR module.

- Application profile extension

The application profile extension is not supported for EJB classes that are packaged in WAR modules.

## Stub generation

Remote access of EJB methods requires the use of client-side stub classes. For most client environments, the product runtime automatically generates the required stub classes. One exception is the thin client environment. For thin clients, the stub classes must be manually generated and packaged with the client.

Use the createEJBStubs tool to generate stubs when the EJB content is packaged in a WAR module, regardless of the EJB version.

See the topic, Create stubs command, for more information.

**Note:** When packaging EJB 2.1 classes in a WAR module, do not include any stub classes generated by the EJBDeploy tool. These stub classes are different than the stub classes automatically generated by the product run time and can cause failures. In most situations the automatically generated stub classes are sufficient. The exception is if a component in the web module must make a remote method invocation on an EJB 2.1 class packaged in another JAR module. In this case, the EJBDeploy generated stub class for the EJB in the other JAR module must be packaged in the WAR module.

## EJB 2.x and 1.x content in a WAR module

Except for entity beans, EJB 2.x and 1.x content is supported in a WAR module.

A 2.x or 1.x module packaged inside a WAR file requires an `ejb-jar.xml` deployment descriptor at version 2.x or 1.x in the `WEB-INF` directory of the WAR module. If XMI bindings and extension files are present, you must also package these bindings and files in the `WEB-INF` directory of a WAR module.

Session beans and message driven beans that you implement according to the 2.x or 1.x coding style can be packaged inside a WAR module.

Both bean managed persistence (BMP) and container managed persistence (CMP) entity beans are not supported in a WAR module.

The application profiling and access intent services are not supported in a WAR module. Session beans found in a WAR module cannot access application profiling tasks.

EJB content that you implement according to both the 3.x coding style and the 2.x and 1.x coding styles, can be packaged together in a single WAR module. However, in this case, you must declare any bindings and extensions information with the XML version of the files, not the XMI version.

## Moving existing EJB content from EJB JAR modules into WAR modules

One approach is to put the existing EJB JAR file in the `WEB-INF/lib` directory of the WAR file. Then, remove the descriptor files from the `META-INF` directory of the JAR file and place them in the `WEB-INF` directory of the WAR file.

A second approach is to put the class files from the EJB JAR file in the correct location under the `WEB-INF/classes` directory in the WAR module. Then, remove the descriptor files from the `META-INF` directory of the JAR file and place them into the `WEB-INF` directory of the WAR file.

If multiple EJB JAR modules are moved into a single WAR module, you must merge the contents of each of the descriptor files previously found in the `META-INF` directories of the EJB JAR modules into the single

version of the descriptor files that are now placed in the WEB-INF directory of the WAR file. Examples of descriptor files that may be merged include, but are not limited to, ejb-jar.xml, ibm-ejb-jar-bnd.xml, ibm-ejb-jar-ext.xml, and ibm-ejb-jar-ext-pme.xml.

You must inspect the references declared by the various components in the WAR module, both EJB and non-EJB, to ensure that they do not conflict with each other, since everything in the WAR module shares a single component name space.

You must modify the bindings and extension XMI files that are moved from an EJB JAR module to a WAR module in several places to remove references to META-INF/ejb-jar.xml and replace them with WEB-INF/ejb-jar.xml.

### EJB function that is supported in EJB JAR modules, but not in WAR modules

The following EJB function is not supported in WAR modules:

- BMP and CMP entity beans
- Pre EJB 3.1 style startup beans

  **Attention:** Singleton startup beans defined by EJB 3.1 are supported.

If an entity bean is placed in a WAR module, error messages display, and the application fails to start. For example, the foo entity bean is placed in the foo.war module in the FooApp application. This results in the following messages:

```
CWMDF0025E: Entity beans in EJB web application archive (WAR) modules are not allowed,
 per the EJB 3.1 specification.
WSVR0039E: Unable to start EJB JAR, foo.war: Entity beans in EJB web application archive
 (WAR) modules are not allowed, per the EJB 3.1 specification. The foo bean in the foo.war module
 must be moved to a stand-alone EJB module. Examine the log to see a full list of invalid entity
 beans in a WAR module.
```

## EJB 3.x module packaging overview

This topic describes application packaging when you use Enterprise JavaBeans (EJB) 3.x beans.

Packaging applications that use EJB 3.x beans is similar to the assembly requirements for Java Platform, Enterprise Edition (Java EE) 1.4 applications: components are packaged into modules, and modules are packaged into application enterprise archive (EAR) files. The components and modules both have describing metadata provided in an Extensible Markup Language (XML) deployment descriptor. The EJB 3.x specifications support an additional method to describing metadata and for packaging persistence units.

The EAR file is a package file format similar to a .zip or .tar file format. The EAR file can be visualized as a collection of logical directories and files that are packaged together into a simple file. Each EAR file includes one or more Java EE module files, which can include the following modules:

- Java application archive (JAR) files for EJB modules. Java EE application client modules and utility class modules.
- Web application archive (WAR) files for web modules, or EJB content. The WAR file must be version 2.5 or higher to contain EJB content.
- Other technology-specific modules such as resource application archive (RAR) files and other types of modules.

## EJB modules without deployment descriptors

You can package EJB modules without a deployment descriptor if you are using EJB 3.x beans. To do this, you must create a JAR file or WAR file with metadata in an annotation which is located in the EJB component. EJB 3.x beans do not need an entry in the `ejb-jar.xml` file for metadata that you have defined through annotations.

With EJB 3.0, the default was to scan annotations during the installation of an EJB 3.0 module. For WebSphere Application Server, Version 8.0, the default is not to scan pre-Java EE 5 modules during the application installation or at server startup.

To preserve backward compatibility with both the Feature Pack for EJB 3.0 and the Feature Pack for Web Services, you have a choice whether to scan legacy web modules for additional metadata. A server level switch is defined for each feature pack scan behavior. If the default is not appropriate, the switch must be set on each server and administrative server that requires a change in the default. The switches are server custom properties com.ibm.websphere.webservices.UseWSFEP61ScanPolicy={true|false} and com.ibm.websphere.ejb.UseEJB61FEPScanPolicy={true|false}. To define these properties in the administrative console click **Application servers** > ***server name*** > **Process definition** > **Java Virtual Machine** > **Custom properties**.

## EJB modules with deployment descriptors

You can continue to use EJB modules with deployment descriptors. Modules with deployment descriptors can support any EJB specification version level, including EJB 3.x, but generally these descriptors should reflect the implementation requirements of the components in the module.

An EJB module can have an EJB 3.x, 2.x, or 1.x deployment descriptor.

For EJB 2.x or 1.x deployment descriptors, it is assumed that the deployment descriptor contains the full metadata for the module, and no additional scanning of annotation metadata occurs.

The EJB container annotation scanning is performed on EJB modules that either have no deployment descriptor or have an `ejb-jar.xml` deployment descriptor at the EJB 3.0 schema level with the metadata-complete XML attribute set to false or omitted. See the Annotation scanning behavior section for the complete set of rules used by the server to determine if annotation scanning is performed.

**Note:** You cannot scan for component annotation metadata contained within shared libraries defined using the WebSphere Application Server system management shared library feature. However, content defined as a BLA Asset is scanned for annotation data.

## Annotation scanning behavior

The server can inspect the class files in the module for annotation content. The server searches for annotation content that might define a component, a reference to a resource, or a particular behavior. For example, annotations might be used to define an EJB component, or to declare a reference to a data source that must be used by an EJB component, or to declare the transactional or security attributes that are associated with an EJB method. This inspection process is referred to as annotation scanning. If the class files in the module contain annotations that must be respected by the server, then the server must be configured so that annotation scanning occurs. If the class files in the module do not contain annotations, then for performance reasons you can configure the server so that annotation scanning does not occur.

The server uses the following criteria to determine whether it scans content for annotations:

- Whether the ejb-jar.xml deployment descriptor file exists
- Version of the ejb-jar.xml deployment descriptor, when it is exists

- Value of the metadata-complete setting in the ejb-jar.xml deployment descriptor, when it exists
- Version of the web.xml deployment descriptor, when the EJB content is packaged in a WAR module, and the ejb-jar.xml deployment descriptor does not exist
- Value of the metadata-complete setting in the web.xml deployment descriptor, when the EJB content is packaged in a WAR module, and the ejb-jar.xml deployment descriptor does not exist

The following tables indicate how the decision to scan, or not scan, annotations is made for EJB content that is packaged in an EJB JAR module or a WAR module.

*Table 95. Annotation scanning for EJB content packaged in an EJB JAR module. Annotation scanning for EJB content packaged in an EJB JAR module*

| ejb-jar.xml | metadata-complete value in ejb-jar.xml | Are annotations scanned? |
|---|---|---|
| Exists, with a version of 2.x or lower | NA | No |
| Exists, with a version of 3.x or higher | true | No |
| Exists, with a version of 3.x or higher | false (or omitted) | Yes |
| Does not exist | NA | Yes |

*Table 96. Annotation scanning for EJB content packaged in a WAR module. Annotation scanning for EJB content packaged in a WAR module*

| ejb-jar.xml file | metadata-complete value in ejb-jar.xml | web.xml file | metadata-complete value in web.xml | Are annotations scanned? |
|---|---|---|---|---|
| Exists, with a version of 3.x or higher | true | NA | NA | No |
| Exists, with a version of 3.x or higher | false (or omitted) | NA | NA | Yes |
| Exists, with a version of 2.x or lower | NA | NA | NA | No |
| Does not exist | NA | Exists, with a version of 2.5 or higher | true | No |
| Does not exist | NA | Exists, with a version of 2.5 or higher | false (or omitted) | Yes |
| Does not exist | NA | Exists, with a version of 2.4 or lower | NA | No |
| Does not exist | NA | Does not exist | NA | Yes |

**Note:**

It is important to understand the distinction between the metadata-complete attribute of the ejb-jar element of the `ejb-jar.xml` deployment descriptor, and the metadata-complete install setting that may be specified during the application or module installation process.

The metadata-complete attribute of the ejb-jar element of the `ejb-jar.xml` file is an XML attribute. It is used by the server to determine if classes must be scanned for annotation data, as just described by the rules in the Annotation Scanning For EJB Content tables.

In contrast, the metadata-complete setting that may be specified at install time is used by the server to help generate the `ejb-jar.xml` file. If no `ejb-jar.xml` file exists in the module, and the metadata-complete install setting is assigned a value of true, then the server scans for annotation content and uses that to generate an `ejb-jar.xml` file, and then sets the metadata-complete XML attribute in that file to a value of true.

## Persistence units

Persistence units, including the `persistence.xml` file and the classes associated with it, can be packaged in the module for which they are required. They can also be packaged in the separate utility JAR file that is packaged in the EAR file with its dependent module.

When a separate utility JAR file is packaged, it is necessary for the module that desires it to use the persistence units to declare a dependency on the utility JAR file using the typical MANIFEST. MF Class-Path: declarations. See the example scenario for this packaging method under the section in this topic called "Session facades used for persistence scenario"

**Note:** Packaging of persistence units contained within shared libraries defined using the WebSphere Application Server system management shared library feature is not supported at this time.

## Application packaging

You can mix EJB 2.x and earlier beans with EJB 3.x beans in the same application. However, EJB 3.x beans are not recognized in EJB 2.x or EJB 1.x modules.

In the case that the EAR file only contains the JAR and web application archive (WAR) files, and no `application.xml` file, the product provides a default J2EE 1.4 deployment descriptor that is based on the following defaults that are outlined in the Java EE specification:

- The application name is assumed to be the name of the EAR file, but with the EAR file extension removed.
- Files that are ending in .war are assumed to be web modules. The context root of the web module is the name of the file that is relative to the root of the application package, but with the WAR file extension removed.
- Files that are ending in .jar that are not in the /lib directory, and that contain either an `ejb-jar.xml` file or at least one class that defines a @Stateful, @Stateless, @Singleton, or @MessageDriven annotation, are assumed to be EJB modules.
- Other JAR files that are not in the /lib directory are not assumed to be EJB modules.

If the application archive file contains an `application.xml` descriptor, processing occurs according to the directives in that descriptor.

#### AutoLink

AutoLink provides the ability to attempt to automatically resolve EJB references to components contained with an EAR file, without having to specify a JNDI binding name. This simplifies application deployment with large numbers of beans and references if they are unique and unambiguous.

**Restriction:** AutoLink should not be used for references to components deployed on a cluster.

## JPA packaging

It is recommend that persistence units be packaged in separate JAR files to make them more accessible and reusable. These can be tested outside the container, with or without actual database persistence occurring. Persistence units can be included in stand-alone applications or into EAR files as utility JAR files. Because of the variety of use cases and potential performance issues when scanning large quantities of classes, it is recommended that the persistence unit defines the classes of the persistence units.

## Session facades used for persistence scenario

A common pattern is to use session facades for persistence. Using session bean facades to drive JPA is supported. The EntityManager interface is not thread safe, therefore, servlets should never inject @PersistenceContext. Servlets must either use the facade pattern or use an EntityManagerFactory instance to create an EntityManager on each request.

It is recommended that JPA persistence units be defined in a separate JAR file, apart from the session bean facades. Not only is this a best practice that gives greater flexibility in sharing, it also avoids problems mixing JPA and non-JPA annotated classes.

Typically, a JAR file is created to hold the entity classes and the JPA `persistence.xml` definition and added to the EAR file as a utility JAR file. The EJB 3.x module adds a dependency on the JAR file by declaring it in the EJB 3.x module MANIFEST.MF. For example, if an EAR contains a `TradeApp.ear`, `TradeWeb.war`, `EJB3Trade.jar`, and `TradeInfo.jar` file, the `EJB3Trade.jar` file would have a MANIFEST.MF that looks like the following:

```
Manifest-Version: 1.0
Class-Path: TradeInfo.jar
```

The session facade in the `EJB3Trade.jar` file refers to JPA entity classes and persistence units in the `TradeInfo.jar` file. The web application defined in the `TradeWeb.war` file can do the same to work with the JPA entity objects as Data Transfer Objects flowing between the web and EJB container tiers.

### Cross-tier and cross version session bean reference scenario

There are several ways to define and use references to EJB 3.x session beans. For EJB 3.x session to session, the @EJB injection target can be used. For cross-tier, for example, web application to EJB 3.x session, or cross-version, for example, EJB 2.1 session to EJB 3.x session, an XML deployment descriptor reference can be used to define ejb-refs and ejb-local-refs. There are two variations of these, depending on whether an EJB 3.x business interface is referred to, or a pre-EJB 3.x component-style interface that also defines an EJBLocalHome is referred to. Web applications and client applications can also use the @EJB annotation if the component being referenced can be resolved using autolink.

For migration scenarios where session beans are being converted from EJB 2.1 beans to EJB 3.x beans, the pattern is typically to edit the Session bean class, replace the *implements SessionBean* with *implements the business interface*, remove *extends EJBLocalObject* from the local interface and non-business throws clauses, and add the @Stateful @Local @LocalHome(<localhome>.class) or similar annotations. Existing ejb-refs and ejb-local-refs are bound to the new implementation of the session bean.

**Note:** The default binding name does change.

The previous scenario uses an EJB 2.1-style client pattern with an EJB 3.x-style session bean implementation. For a more current client style, the client-side can be cleaned up to look up the session bean business interface directly, rather than going through a home interface. In this case, it is not necessary to define the @LocalHome(<localhome>.class) annotation. You can use a variant definition of ejb-ref and ejb-local-ref to do this. Use a *null* value for the local-home element value and bind the ejb-local-ref to the session bean's ejblocal: binding rather than the home binding. For example:

```
<ejb-local-ref id="EJBLocalRef_1154112538064">
 <description>com.ibm.persistence.ejb3.order.facadecom.ibm.persistence.ejb3.order.facade</description>
 <ejb-ref-name>ejb/OrderEJB</ejb-ref-name>
 <ejb-ref-type>Session</ejb-ref-type>
 <local-home></local-home>
 <local>com.ibm.persistence.ejb3.order.facade.OrderProcessor</local>
</ejb-local-ref>
```

The client code also must be adjusted to do the appropriate casting for the object being looked up. In this case, the business interface instead of the home interface:

```
try {
 InitialContext ctx = new InitialContext();
 orderProcessor = (OrderProcessor)ctx.lookup("java:comp/env/ejb/OrderEJB");
}
catch(Exception e)  {
 e.printStackTrace(System.out);
 throw new ServletException(e);
}
```

## Defining container transactions for EJB modules

Container transaction properties specify how an Enterprise JavaBeans (EJB) container is to manage transaction scopes for the enterprise bean method invocations.

### About this task

A transaction attribute is mapped to one or more methods. Some container transaction settings are not available for all enterprise beans. Also, some methods are not available for particular transaction settings and beans. These rules have been implemented in the Add Container Transaction wizard based on the EJB specification.

To complete this task see the topic, Defining container transactions for EJB modules, in the assembly tool information center.

## References in application deployment descriptor files

References are logical names used to locate external resources for enterprise applications. References are defined in the application's deployment descriptor file. At deployment, the references are bound to the physical location (global Java Naming and Directory Interface (JNDI) name) of the resource in the target operational environment.

This product supports the following types of references:
- An Enterprise JavaBeans (EJB) reference is a logical name used to locate the home interface of an enterprise bean.
- A resource reference is a logical name used to locate a connection factory object.

These objects define connections to external resources such as databases and messaging systems. The container makes references available in a JNDI naming subcontext. By convention, references are organized as follows:
- EJB references are made available in the java:comp/env/ejb subcontext.
- Resource references are made available as follows:
  - JDBC data source references are declared in the java:comp/env/jdbc subcontext.
  - JMS connection factories are declared in the java:comp/env/jms subcontext.
  - Mail connection factories are declared in the java:comp/env/mail subcontext.
  - URL connection factories are declared in the java:comp/env/url subcontext.

## EJB references

Use this page to view and modify the Enterprise JavaBeans (EJB) references to the enterprise beans. References are logical names used to locate external resources for enterprise applications. References are defined in the application's deployment descriptor file. At deployment, the references are bound to the physical location (global Java Naming and Directory Interface (JNDI) name) of the resource in the target operational environment.

If your application defines EJB references, for **Map EJB references to beans**, specify JNDI names for enterprise beans that represent the logical names that are specified in EJB references. Each EJB reference defined in the application must be bound to an EJB file before clicking Finish in the Summary panel.

If the EJB reference is from an EJB 3.x, Web 2.4, Web 2.5, or Client 5.0 module, the JNDI name is optional. If the **Allow EJB reference targets to resolved automatically** option is enabled, the JNDI name is optional for all modules. The runtime provides a container default or automatically resolves the EJB reference if a binding is not provided.

To view this administrative console page, click **Applications** > **Application Types** > **WebSphere enterprise applications** > **application_name** > **EJB references**.

Values are displayed for Lookup name and EJB Link if they are configured in the application. Only one of these values is allowed. If both are set, the value must be overridden by a target resource JNDI name.

**Attention:** If an application is running, changing an application setting causes the application to restart. On stand-alone servers, the application restarts after you save the change. On multiple-server products, the application restarts after you save the change and files synchronize on the node where the application is installed. To control when synchronization occurs on multiple-server products, deselect **Synchronize changes with nodes** on the Console preferences page.

### Module
Specifies the name of the Enterprise JavaBeans module used by your application.

### Bean
Specifies the name of an enterprise bean that is contained by the module.

### URI
Specifies location of the module relative to the root of the application EAR file.

### Resource Reference
Specifies the name of the EJB reference that is used in the enterprise bean, if applicable, and declared in the deployment descriptor of the application module.

### Class
Specifies the name of a Java class associated with this enterprise bean.

### Target Resource JNDI Name
Specifies the JNDI name of the enterprise bean.

This is a data entry field. To modify the JNDI name bound to this bean, type the new name in this field, then select **OK**.

**Data type** String

## EJB JNDI names for beans
Use this page to view and modify the Java Naming and Directory Interface (JNDI) names of non-message-driven enterprise beans in your application or module.

If your application uses Enterprise JavaBeans (EJB) 2.1 and earlier modules, on the Provide JNDI names for beans panel, specify a JNDI name for each enterprise bean in every EJB 2.1 and earlier module. You must specify a JNDI name for every EJB 2.1 and earlier enterprise bean defined in the application. For example, for the EJB module MyBean.jar, specify MyBean.

The JNDI name for an EJB module can be used for both EJB 3.x modules and pre-EJB 3.0 modules. For a pre-EJB 3.0 module, you need to provide a JNDI name for the bean. For an EJB 3.x module, you have three options

- Provide no JNDI names at all
- Select the radio button to provide a JNDI name for the bean, or
- Select the radio button to provide local or remote home JNDI names.

If no JNDI name is provided, the run time provides a default value. If JNDI name for the bean is provided, you cannot provide any JNDI name for business interface in the Provide JNDI names for business interfaces panel.

To view this administrative console page, click **Applications** > **Application Types** > **WebSphere enterprise applications** > **application** > **EJB JNDI names**.

**Attention:** If an application is running, changing an application setting causes the application to restart. On stand-alone servers, the application restarts after you save the change. On multiple-server products, the application restarts after you save the change and files synchronize on the node where the application is installed. To control when synchronization occurs on multiple-server products, deselect **Synchronize changes with nodes** on the Console preferences page.

### Module
Specifies the name of the Enterprise JavaBeans module used by your application.

### Bean
Specifies the name of an enterprise bean that is contained by the module.

### URI
The Uniform Resource Identifier (URI) specifies the location of the module archive relative to the root of the application EAR.

### Target Resource JNDI name
Specifies the Java Naming and Directory Interface (JNDI) name of the enterprise bean.

This is a data entry field. To modify the JNDI name bound to this bean, type the new name in this field, then select **OK**.

**Data type** String

## Bind EJB business settings
Use this administrative console page to specify Java Naming and Directory (JNDI) name bindings for each enterprise bean with a business interface in an EJB module. Each enterprise bean with a business interface in an EJB module must be bound to a JNDI name. For any business interface that does not provide a JNDI name, or if its bean does not provide a JNDI name, a default binding name is provided. If its bean provides a JNDI name, the default JNDI name for the business interface is provided on top of its bean JNDI name by appending the package-qualified class name of the interface.

If you specify the JNDI name for a bean in the Provide JNDI names for beans page, do not specify any business interface JNDI name in this page for the same bean. If you do not specify the JNDI name for a bean in the Provide JNDI names for beans page, you can optionally specify a business interface JNDI name. If you do not specify a business interface JNDI name, the run time provides a container default.

To view this page in the administrative console, click **Applications** > **Application Types** > **WebSphere enterprise applications** > ***application_name*** > **Bind EJB business**.

**Attention:** If an application is running, changing an application setting causes the application to restart. On stand-alone servers, the application restarts after you save the change. On multiple-server products, the application restarts after you save the change and files synchronize on the node where the application is installed. To control when synchronization occurs on multiple-server products, deselect **Synchronize changes with nodes** on the Console preferences page.

### Module
Specifies the EJB module that contains the enterprise beans that bind to the JNDI name.

### Bean
Specifies the enterprise bean that binds to the JNDI name.

### URI
The Uniform Resource Identifier (URI) specifies the location of the module archive relative to the root of the application EAR.

### Business Interface
Specifies the enterprise bean business interface in an EJB module.

For a no-interface view, the business interface value is an empty string ("").

### JNDI Name
Specifies the JNDI name associated with the enterprise bean business interface in an EJB module.

---

# Deploying EJB 3.x enterprise beans

## EJB module settings
Use this page to configure and manage a specific deployed EJB module.

**Note:** You cannot start or stop an individual EJB module for modification. You must start or stop the appropriate application entirely.

To view this administrative console page, click **Applications** > **Application Types** > **WebSphere enterprise applications** > **application_name** > **Manage Modules** > **module_name**.

**Attention:** If an application is running, changing an application setting causes the application to restart. On stand-alone servers, the application restarts after you save the change. On multiple-server products, the application restarts after you save the change and files synchronize on the node where the application is installed. To control when synchronization occurs on multiple-server products, deselect **Synchronize changes with nodes** on the Console preferences page.

### URI
Specifies location of the module relative to the root of the application EAR file. The URI must match the URI of a ModuleRef URI in the deployment descriptor of the deployed application (EAR).

### Alternate deployment descriptor
Specifies an alternate deployment descriptor for the module as defined in the application deployment descriptor according to the Java Platform, Enterprise Edition (Java EE) specification.

### Starting weight
Specifies the order in which modules are started when the server starts. The module with the lowest starting weight is started first.

If the application deployment descriptor specifies the `<initialize-in-order>true</initialize-in-order>` element, the default starting weights reflect the order that is specified in the deployment descriptor. Otherwise, the defaults are determined based on module type (RAR modules start before EJB modules, which start before web modules).

| **Range** | Greater than 0 |

## Directory conventions
References in product information to *app_server_root*, *profile_root*, and other directories imply specific default directory locations. This topic describes the conventions in use for WebSphere Application Server.

### Default product locations (distributed)

The following file paths are default locations. You can install the product and other components or create profiles in any directory where you have write access. Multiple installations of WebSphere Application

Server - Express products or components require multiple locations. Default values for installation actions by root and nonroot users are given. If no nonroot values are specified, then the default directory values are applicable to both root and nonroot users.

*app_client_root*

*Table 97. Default installation root directories for the Application Client for IBM WebSphere Application Server.*

*This table shows the default installation root directories for the Application Client for IBM WebSphere Application Server.*

| User | Directory |
|---|---|
| Root | AIX `/usr/IBM/WebSphere/AppClient` (Java EE Application client only)<br>HP-UX Linux Solaris `/opt/IBM/WebSphere/AppClient` (Java EE Application client only)<br>Windows `C:\Program Files\IBM\WebSphere\AppClient` |
| Nonroot | AIX HP-UX Linux Solaris *user_home*`/IBM/WebSphere/AppClient` (Java EE Application client only)<br>Windows `C:\IBM\WebSphere\AppClient` |

*app_server_root*

*Table 98. Default installation directories for WebSphere Application Server.*

*This table shows the default installation directories for WebSphere Application Server - Express.*

| User | Directory |
|---|---|
| Root | AIX `/usr/IBM/WebSphere/AppServer`<br>HP-UX Linux Solaris `/opt/IBM/WebSphere/AppServer`<br>Windows `C:\Program Files\IBM\WebSphere\AppServer` |
| Nonroot | AIX HP-UX Linux Solaris *user_home*`/IBM/WebSphere/AppServer`<br>Windows *user_home*`\IBM\WebSphere\AppServer` |

*component_root*

The component installation root directory is any installation root directory described in this topic. Some programs are for use across multiple components—in particular, the Web Server Plug-ins, the Application Client, and the IBM HTTP Server. All of these components are part of the product package.

*gskit_root*

IBM Global Security Kit (GSKit) can now be installed by any user. GSKit is installed locally inside the installing product's directory structure and is no longer installed in a global location on the target system. The following list shows the default installation root directory for Version 8 of the GSKit, where *product_root* is the root directory of the product that is installing GSKit, for example IBM HTTP Server or the web server plug-in.

AIX HP-UX Linux Solaris

*product_root*`/gsk8`

Windows

*product_root*`\gsk8`

*profile_root*

*Table 99. Default profile directories.*

*This table shows the default directories for a profile named profile_name on each distributed operating system.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/AppServer/profiles/*profile_name*<br>HP-UX Linux Solaris /opt/IBM/WebSphere/AppServer/profiles/*profile_name*<br>Windows C:\Program Files\IBM\WebSphere\AppServer\profiles*profile_name* |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/AppServer/profiles<br>Windows *user_home*\IBM\WebSphere\AppServer\profiles |

### *plugins_root*

*Table 100. Default installation root directories for the Web Server Plug-ins.*

*This table shows the default installation root directories for the Web Server Plug-ins for WebSphere Application Server.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/Plugins<br>HP-UX Linux Solaris /opt/IBM/WebSphere/Plugins<br>Windows C:\Program Files\IBM\WebSphere\Plugins |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/Plugins<br>Windows C:\IBM\WebSphere\Plugins |

### *wct_root*

*Table 101. Default installation root directories for the WebSphere Customization Toolbox.*

*This table shows the default installation root directories for the WebSphere Customization Toolbox.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/Toolbox<br>HP-UX Linux Solaris /opt/IBM/WebSphere/Toolbox<br>Windows C:\Program Files\IBM\WebSphere\Toolbox |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/Toolbox<br>Windows C:\IBM\WebSphere\Toolbox |

### *web_server_root*

*Table 102. Default installation root directories for the IBM HTTP Server.*

*This table shows the default installation root directories for the IBM HTTP Server.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/HTTPServer<br>HP-UX Linux Solaris /opt/IBM/HTTPServer<br>Windows C:\Program Files\IBM\HTTPServer |

*Table 102. Default installation root directories for the IBM HTTP Server (continued).*

*This table shows the default installation root directories for the IBM HTTP Server.*

| User | Directory |
|---|---|
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/HTTPServer<br>Windows C:\IBM\HTTPServer |

# Deploying EJB modules

When you deploy an Enterprise JavaBeans (EJB) module, you install that module on a server that has been configured to support deployed modules.

## Before you begin

Assemble one or more EJB modules, assemble one or more web modules, and assemble them into a Java EE application.

For an overview about the changes to the EJB deployment model for EJB 3.x, see the topic EJB 3.x deployment overview.

## Procedure

1. Prepare the deployment environment. See the topic Preparing to host applications.
2. Update the configuration for each EJB module as needed for the deployment environment.
3. Required: If a module has dependencies on Java 5-specific extensions, such as generics, annotations, and so on, then you must run the EJBDeplolycommand-line tool separately and before installing the module or application containing it. This is because the administrative console and the wsadmin command-line tool do not allow for specifying the ejbdeploy -complianceLevel 5.0 option.

   It is only necessary to run the EJBDeploy tool for EJB 2.1 modules containing entity beans.
4. Address potential interoperability issues.

   There can be unexpected results if a WebSphere stack product, or another product, that runs on a version of Application Server that does not support EJB 3.x attempts to remotely invoke a method on an EJB 3.x compliant enterprise bean on a separate server that is running a version Application Server that supports EJB 3.x. If these products attempt to invoke a method through the enterprise bean's EJB 3.x remote business interface, they might encounter exceptions that were introduced in EJB 3.x that will be pushed back to the environment that is not EJB 3.x compliant.

   This scenario could also be an issue for an administrator of an environment that includes a combination of stack products that contain a mixture of EJB 3.x compliant and non-compliant instances of Application Server.

   The following is a list of the exception classes that have been introduced in EJB 3.0:

   - javax.ejb.ConcurrentAccessException
   - javax.ejb.EJBAccessException
   - javax.ejb.EJBTransactionRequiredException
   - javax.ejb.EJBTransactionRolledbackException
   - javax.ejb.NoSuchEJBException

   a. Ensure that Application Server is updated to 7.0.0.3.

   b. Manually copy the <*app_server_root*>/runtimes/ejb3exceptions.jar file from Application Server to a directory on each of the stack products installations, or other product installations, that you will use as the EJB 3.x client.

c. Ensure that the directory that contains the ejb3exceptions.jar file is in the class path. One possible location for the JAR file that would satisfy this requirement is the <*app_server_root*>/lib directory on a server that is not EJB 3.x compliant.

   **Note:** Just like the EJB thin client jars, if an update becomes available, users must copy the ejb3exceptions.jar file again after installing the version of the WebSphere Application Server containing the updated version.

5. Deploy the application. See the topic Deploying and administering enterprise applications.

### What to do next

If you specify that the EJBDeploy tool be run during application installation and the installation fails with a NameNotFoundException message, ensure that the input Java archive (JAR) or enterprise archive (EAR) file does not contain source files. Either remove the source files or include all dependent classes and resource files on the class path. If there are source files in the input JAR or EAR file, the EJB deployment tools runs a rebuild before generating the deployment code.

If the module deploys successfully, test and debug the module. See the topic Diagnosing problems (using diagnosis tools).

## EJB 3.0 and EJB 3.1 deployment overview

Learn about the Enterprise JavaBeans (EJB) 3.0 and 3.1 deployment model, including *Just-In-Time* (JIT) deployment.

All Java Enterprise Edition (Java EE ) application server products have some form of EJB deployment phase in which your application is customized to run in that particular implementation of the application server. Typically, this is accomplished by a deployment tool that is specific to the application server and generates code to bridge your EJB interface and implementation code to the application server's implementation for an EJB container. Some application server products' deployment tools alter the bytecodes of your application classes, rather than generating code, but the end result is similar.

Application Server bridges your EJB interface with its implementation by generating code that encapsulates your EJB implementation classes, connecting them to Application Server's EJB container. This enables the EJB container to host your enterprise beans and provide services to them. If one or more of your enterprise beans has remote interfaces defined, Application Server generates additional code to provide the remote function.

For more information about packaging your EJB module, see the topic that covers the EJB 3.x module packaging overview.

### EJBDeploy Tool

Historically, EJB deployment in the Application Server product has been performed by the EJBDeploy tool, which is included with WebSphere Application Server and packaged with the development tools for the WebSphere products.

The EJBDeploy tool introspects the external interfaces for your enterprise beans, generates the wrapper code as .java files, and compiles the code using the javac compiler to produce .class files that are packaged in your EJB module with your application code. The EJBDeploy tool also runs the rmic tool against the remote EJB interfaces in the application, producing additional *stub* and *tie* class files that interact with the Remote Method Invocation over Internet Inter-ORB Protocol (RMI-IIOP) Object Request Broker (ORB), providing remote object support.

For modules previous to EJB 3.0, you ran the EJBDeploy tool when you installed the application on Application Server or before you installed the application from the command-line tool or a development tool.

## Just-In-Time (JIT) deployment

EJB 3.0 support in Application Server introduced a new feature called JIT deployment.

With JIT deployment, the EJB container dynamically generates the wrapper, stub, and tie classes in-memory when the application is running. Additionally, the web container and application client containers dynamically generate the stub class that is required for remote EJB invocations.

Effectively, this means that you do not need to process EJB 3.0 or 3.1 modules, web modules that invoke EJB 3.0 or 3.1 beans, or client modules that invoke EJB 3.0 or 3.1 beans through the EJBDeploy tool before you run them in Application Server.

## createEJBStubs tool

In most cases the Just-In-Time deployment feature can dynamically generate the RMI-IIOP stub classes that are required for invocation of remote EJB interfaces. There are some instances in which these stub classes are not dynamically generated. For EJB 3.0 or 3.1 clients that are not running inside an EJB 3.x enabled web container, EJB container, or client container, you must generate the stub classes with the createEJBStubs tool and ensure that the generated stubs are available in the client environment's class path. Typically, you would accomplish this by copying the generated stubs to the location where the client's business interface class resides.

The createEJBStubs tool must be used to generate client-side stubs for the following environments:

- "Bare" Java Standard Edition (SE) clients, where a Java SE Java Virtual Machine (JVM) is the client environment.
- Containers in Application Server environments prior to Version 7 that do not have the Feature Pack for EJB 3.0 applied.
- Environments that are not WebSphere Application Server environments.

## Interoperability

There can be unexpected results if a WebSphere stack product, or another product, that runs on a version of Application Server that does not support EJB 3.0 or 3.1 attempts to remotely invoke a method on an EJB 3.x compliant enterprise bean on a separate server that is running a version Application Server that supports EJB 3.0 or 3.1. If these products attempt to invoke a method through the enterprise bean's EJB 3.x remote business interface, they might encounter exceptions that were introduced in EJB 3.0 that will be pushed back to the environment that is not EJB 3.x compliant.

This scenario could also be an issue for an administrator of an environment that includes a combination of stack products that contain a mixture of EJB 3.x compliant and non-compliant instances of Application Server.

The following is a list of the exception classes introduced in EJB 3.0:

- javax.ejb.ConcurrentAccessException
- javax.ejb.EJBAccessException
- javax.ejb.EJBTransactionRequiredException
- javax.ejb.EJBTransactionRolledbackException
- javax.ejb.NoSuchEJBException

Refer to the EJB module deployment step to address potential interoperability issues.

### EJB 2.x Modules

EJB 2.x modules that have been converted to be EJB 3.0 or EJB 3.1 modules should have all WebSphere Application Server generated files (including stub and tie classes) removed prior to EJB deployment in the Application Server product.

## EJBDEPLOY relationships – troubleshooting tips

Use this information to troubleshoot information for EJBDEPLOY problems.

### The converter that is defined for the primary key is not invoked on its foreign key value

The mapping for primary key fields to database columns may use a converter to transform the key values. If a container-managed persistence (CMP) bean uses a converter to map its primary key, and that bean has a relationship where the bean at the other end holds a foreign key, the mapping for the foreign key will not use the converter.

The following errors might occur, indicating that the converter defined for the primary key is not invoked on its foreign key value. During the run of the ejbDeploy command , you receive the following message:

```
No type mapping defined for Java datatype1 to Database datatype2
```

During run time, the application does not find the CMP bean at the other end of the relationship.

To work around this limitation, define your own foreign key in the database table, and create a mapping that uses the same converter as defined for the primary key on the enterprise beans at the other end of its relationship.

## Directory conventions

References in product information to *app_server_root*, *profile_root*, and other directories imply specific default directory locations. This topic describes the conventions in use for WebSphere Application Server.

### Default product locations (distributed)

The following file paths are default locations. You can install the product and other components or create profiles in any directory where you have write access. Multiple installations of WebSphere Application Server - Express products or components require multiple locations. Default values for installation actions by root and nonroot users are given. If no nonroot values are specified, then the default directory values are applicable to both root and nonroot users.

*app_client_root*

*Table 103. Default installation root directories for the Application Client for IBM WebSphere Application Server.*

*This table shows the default installation root directories for the Application Client for IBM WebSphere Application Server.*

| User | Directory |
|---|---|
| Root | AIX `/usr/IBM/WebSphere/AppClient` (Java EE Application client only)<br>HP-UX Linux Solaris `/opt/IBM/WebSphere/AppClient` (Java EE Application client only)<br>Windows `C:\Program Files\IBM\WebSphere\AppClient` |
| Nonroot | AIX HP-UX Linux Solaris *user_home*`/IBM/WebSphere/AppClient` (Java EE Application client only)<br>Windows `C:\IBM\WebSphere\AppClient` |

*app_server_root*

*Table 104. Default installation directories for WebSphere Application Server.*

*This table shows the default installation directories for WebSphere Application Server - Express.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/AppServer<br>HP-UX Linux Solaris /opt/IBM/WebSphere/AppServer<br>Windows C:\Program Files\IBM\WebSphere\AppServer |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/AppServer<br>Windows *user_home*\IBM\WebSphere\AppServer |

*component_root*

The component installation root directory is any installation root directory described in this topic. Some programs are for use across multiple components—in particular, the Web Server Plug-ins, the Application Client, and the IBM HTTP Server. All of these components are part of the product package.

*gskit_root*

IBM Global Security Kit (GSKit) can now be installed by any user. GSKit is installed locally inside the installing product's directory structure and is no longer installed in a global location on the target system. The following list shows the default installation root directory for Version 8 of the GSKit, where *product_root* is the root directory of the product that is installing GSKit, for example IBM HTTP Server or the web server plug-in.

AIX HP-UX Linux Solaris

*product_root*/gsk8

Windows

*product_root*\gsk8

*profile_root*

*Table 105. Default profile directories.*

*This table shows the default directories for a profile named profile_name on each distributed operating system.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/AppServer/profiles/*profile_name*<br>HP-UX Linux Solaris /opt/IBM/WebSphere/AppServer/profiles/*profile_name*<br>Windows C:\Program Files\IBM\WebSphere\AppServer\profiles*profile_name* |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/AppServer/profiles<br>Windows *user_home*\IBM\WebSphere\AppServer\profiles |

*plugins_root*

*Table 106. Default installation root directories for the Web Server Plug-ins.*

*This table shows the default installation root directories for the Web Server Plug-ins for WebSphere Application Server.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/Plugins<br>HP-UX Linux Solaris /opt/IBM/WebSphere/Plugins<br>Windows C:\Program Files\IBM\WebSphere\Plugins |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/Plugins<br>Windows C:\IBM\WebSphere\Plugins |

*wct_root*

*Table 107. Default installation root directories for the WebSphere Customization Toolbox.*

*This table shows the default installation root directories for the WebSphere Customization Toolbox.*

*web_server_root*

*Table 108. Default installation root directories for the IBM HTTP Server.*

*This table shows the default installation root directories for the IBM HTTP Server.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/HTTPServer<br>HP-UX Linux Solaris /opt/IBM/HTTPServer<br>Windows C:\Program Files\IBM\HTTPServer |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/HTTPServer<br>Windows C:\IBM\HTTPServer |

# Developing EJB 2.x entity beans that use access intents

## Using the AccessIntent API

This task describes how to programmatically retrieve and call the AccessIntent API during the execution of bean managed persistence (BMP) entity bean methods.

### Procedure

1. Look up the access intent service from the namespace. For example:

```
InitialContext ic = new InitialContext();
AccessIntentService aiService = ic.lookup("java:comp/websphere/AppProfile/AccessIntentService");
```

2. From a method of the remote or local component interface of the BMP, get the current AccessIntent object using the javax.ejb.EntityContext. This object is passed to the BMP when the container calls the setEntityContext method. Assume the EntityContext was stored in a variable named myEntityCtx. For example:

```
AccessIntent ai = aiService.getAccessIntent (myEntityCtx);
```

3. Use the get() methods of AccessIntent interface to obtain the wanted information. For example:

```
int concurrency = ai.getConcurrencyControl();
int accessType = ai.getAccessType();
if ( (concurrency == AccessIntent.CONCURRENCY_CONTROL_PESSIMISTIC)
   && (accessType == AccessIntent.ACCESS_TYPE_UPDATE) ) {
     int exclusive = ai.getPessimisticUpdateLockHint();
     // . . .
}
// . . .
```

For a detailed example of the use of the AccessIntent API, see the topic Example: Using IBM extended APIs to share connections between CMP beans and BMP beans..

## Results

**Note:** The access intent object reference retrieved from the java:comp lookup is current for the duration of the method in which the reference was looked up. Depending on how you configured the application profile, subsequent calls of the same method might not retrieve the same access intent reference. You can only look up the object reference during the call of a BMP entity bean method; the reference does not exist during a request on a container managed persistence (CMP) entity bean. Therefore, do not cache access intent object references beyond, or used outside of, the scope of the execution of any given BMP method.

## AccessIntent interface

The AccessIntent interface is available to bean-managed persistence (BMP) entity beans.

A BMP entity bean can get and use an instance of the AccessIntent interface. For more information see “Using the AccessIntent API” on page 757.

### AccessIntent interface

```
package com.ibm.websphere.appprofile.accessintent;

/**
* This interface defines the essential access intents
* available at run time.
*/
public interface AccessIntent {

/**
* Returns the concurrency control intent, which indicates
* the application prefers either pessimistic or optimistic
* concurrency control when accessing the current component
* in the context of the current transaction.
*/
public int getConcurrencyControl();
public final int CONCURRENCY_CONTROL_PESSIMISTIC = 1;
public final int CONCURRENCY_CONTROL_OPTIMISTIC = 2;

/**
* Returns access type intent, which indicates the application
* intends either update or read access of the current component
* in the context of the current transaction.
*/
```

```
public int getAccessType();
public final int ACCESS_TYPE_UPDATE= 1;
public final int ACCESS_TYPE_READ = 2;

/**
* Returns an integer value that indicates that the run time should
* assume that there will be no collision on retrieved rows.
*/
public int getPessimisticUpdateLockHint();
public final static int PESSIMISTIC_UPDATE_LOCK_HINT_NOCOLLISION = 1;
public final static int PESSIMISTIC_UPDATE_LOCK_HINT_WEAKEST_LOCK_AT_LOAD = 2;
public final static int PESSIMISTIC_UPDATE_LOCK_HINT_NONE = 3;
public final static int PESSIMISTIC_UPDATE_LOCK_HINT_EXCLUSIVE = 4;

/*
* Returns an integer value that indicates that the run time should
* assume that there will be collisions on retrieved rows.
*/
public int getPessimisticUpdateLockHint();
public final static int PESSIMISTIC_UPDATE_LOCK_HINT_NOCOLLISION = 1;
public final static int PESSIMISTIC_UPDATE_LOCK_HINT_WEAKEST_LOCK_AT_LOAD = 2;
public final static int PESSIMISTIC_UPDATE_LOCK_HINT_NONE = 3;
public final static int PESSIMISTIC_UPDATE_LOCK_HINT_EXCLUSIVE = 4;

/**
* Returns the collection access intent, which indicates the
* application intends to access the objects returned by the
* currently executing finder in either serial or random fashion.
*/
public int getCollectionAccess();
public final int COLLECTION_ACCESS_RANDOM = 1;
public final int COLLECTION_ACCESS_SERIAL = 2;

/**
* Returns the collection scope, which indicates the maximum
* lifespan of a lazy collection.
*/
public int getCollectionScope();
public final int COLLECTION_SCOPE_TRANSACTION = 1;
public final int COLLECTION_SCOPE_ACTIVITYSESSION = 2;
public final int COLLECTION_SCOPE_TIMEOUT = 3;

/**
* Returns the timeout value in seconds when collectionScope is Timeout.
*/
public int getCollectionTimeout();

/**
* Returns the number of elements the application requests be contained
* in each segment of the element collection returned by the currently
* executing finder.
*/
public int getCollectionIncrement();

/**
* Returns the ReadAheadHint requested by the application for the currently
* executing finder.
*/
public ReadAheadHint getReadAheadHint();

/**
* Returns the number of elements the application requests be contained in
* each segment of a query made on a database.
```

```
*/
public int getResourceManagerPreFetchIncrement();

}
```

# Assembling access intents to EJB 2.x entity beans

## Applying access intent policies to beans

You can apply an access intent policy to an application's entity beans through the assembly tool.

### About this task

Container-managed persistence (CMP) developers can use *access intent* to provide hints on how the application server run time should manage the details of persistence without having to explicitly manage any of the persistence logic from within their application.

Using the access intent service is also an option for programmers who develop bean-managed persistence (BMP) entity beans. Because the only meaningful difference between BMP and CMP components is the mechanism that provides the persistence logic, BMP beans leverage access intent hints in the same manner as the EJB container manages accent intent for CMP beans. This ability becomes especially important when BMP entities and CMP entities want to share connections. BMP beans configured with the same concurrency as the CMP beans and implemented to the same isolation level mapping as the CMP can share connections.

Developers can apply access intent policies to BMP entity beans as well as to CMP entity beans. It is expected that BMP developers use only those access intent attributes that are important to a particular BMP bean. The access intent service interface is bound into the *java:comp namespace* for each particular BMP bean. The access intent policy retrieved from the access intent service is current from the time that the *ejbLoad* process is called until the time that the *ejbStore* process completes its invocation.

**Note:** This is the preferred technique to define access intent policies. Method-level access intent is deprecated in Version 6.0.

### Procedure

1. Start an assembly tool.
2. Optional: Open the Java EE perspective to work with Java EE projects. Click **Window > Open Perspective > Other > Java EE**.
3. Optional: Open the Project Explorer view. Click **Window > Show View > Project Explorer**. Another helpful view is the Navigator view (**Window > Show View > Navigator**).
4. Create a new application EAR file or edit an existing one.

   For example, to change attributes of an existing application, use the import wizard to import an EAR file. To start the import wizard:

   a. Select **File > Import > EAR file > Next**
   b. Select the EAR file.
   c. Create a WebSphere Application Server v6.0 type of Server Runtime. Select **New** to open the New Server Runtime Wizard and follow the instructions.
   d. In the *Target server* field, select *WebSphere Application Server v6.0* type of Server Runtime.
   e. Select **Finish**
5. In the Project Explorer view of the J2EE perspective, right-click **Deployment Descriptor: EJB Module Name** under the EJB module for the bean instance, then select **Open With > Deployment Descriptor Editor**. A property dialog notebook for the EJB project is displayed in the property pane.
6. Select the **Access** tab.

7. In the **Access Intent for Entities 2.x (Bean Level)** panel, select the name of the bean.
8. On the right side of the **Access Intent for Entities 2.x (Method Level)** panel, select **Add**. The **Add Access Intent** panel displays.
9. In the **Access intent name** field, select wsPessimisticUpdate from the drop-down list.
10. Optional: Enter a **Description** to help you remember what this policy does.
11. Optional: Change the **Persistence Option** setting
12. Click **Finish**. The access intent policy for the entity bean is shown in the **Access Intent for Entities 2.x (Bean Level)** panel

# Configuring read-read consistency checking with an assembly tool

Read-read consistency checking only applies to LifeTimeInCache beans whose data is read from another transaction. The product checks that the data is consistent with the data store, and ensures that it is not updated after checking for access intents that are *repeatable read* (RR).

## About this task

For access intents that are *read committed* (RC), the product checks that the data is consistent at the point of checking; it does **not** guarantee that the data does not change after the checking. This makes the behavior of the LifeTimeInCache bean the same as beans that are non-LifeTimeInCache.

To perform this checking, you need to configure CMP entity beans with read-read consistency checking. You can do this using an assembly tool. To learn how to complete this task see the topic, Adding bean-level access intent for entity beans 2.x in the assembly tool information center.

## Example: Read-read consistency checking

Read-read consistency checking only applies to LifeTimeInCache beans whose data is read from another transaction.

### Usage scenario

For the access intents that are for *repeatable read* (RR), this means the product checks that the data is consistent with that in the data store and ensures that no one updates it after the checking. For the Access Intents that are for *read committed* (RC), this means the product checks that the data is consistent at the point of checking, but it does **not** guarantee that the data does not change after the checking. This makes the behavior of the LifeTimeInCache bean the same as non-LifeTimeInCache beans.

You have three options for setting consistency checking, as shown in the following scenarios concerning the calculation of interest in "Ann's" bank account. In each case, the data store is shared by this Enterprise JavaBeans (EJB) container managed persistence (CMP) application to calculate the interest and other applications, such as EJB bean managed persistence (BMP) , Java Database Connectivity (JDBC), or legacy applications. Also in each case, the EJB account is configured as a *long-lifetime* bean.

#### NONE

- The server is started.
- User 1 in Transaction 1 calls Account.findByPrimaryKey("10001"), account data for Ann is read from the database, with a balance of $100.
- Ann’s record is cached by the persistence manager (PM) on the server.
- User 2 writes a JDBC call and changes the balance to $120.
- User 3 in Transaction 2 calls Account.findByPrimaryKey() for account "10001", Ann’s data is read from cache, with a balance of $100.
- Calculate Ann’s interest, but the result might not be correct because of the data integrity issue.

### Read-read checking AT_TRAN_BEGIN

- The server is started.
- User 1 in Transaction 1 calls Account.findByPrimaryKey("10001"), account data for Ann is read from the database, with a balance of $100.
- Ann's record is cached by the persistence manager (PM) on the server.
- User 2 writes a JDBC call and changes the balance to $120.
- User 3 in Transaction 2 calls Account.findByPrimaryKey() for account "10001", Ann's data is read from cache, with a balance of $100.
- PM performs read-read check on Ann's account and finds that the balance of 100 is changed. It issues a database query to retrieve balance of $120, and Ann's data in the cache is refreshed.
- Calculate Ann's interest, proceed with the transaction because data integrity is protected.

### Read-read checking AT_TRAN_END

- The server is started.
- User 1 in Transaction 1 calls Account.findByPrimaryKey("10001"), account data for Ann is read from the database, with a balance of $100.
- Ann's record is cached by the persistence manager (PM) on the server.
- User 2 writes a JDBC call and changes the balance to $120.
- User 3 in Transaction 2 calls Account.findByPrimaryKey() for account "10001", Ann's data is read from database, with balance of $100.
- Calculate Ann's interest.
- During end of transaction 2, PM performs read-read check on Ann's account and finds that the balance of 100 is changed.
- PM rolls back the transaction and invalidates the cache. The transaction fails and again data integrity is protected.

## Access intent service

Access intent is an application server runtime service that enables you to precisely manage an application's persistence.

The access intent service defines a set of declarative annotations used by the Enterprise JavaBeans (EJB) container and its agents to make performance optimizations for entity bean access. These annotations are organized into sets called *access intent policies*.

Access intent policies contain a set of annotations considered as hints by the EJB container and its agents. Most access intent policies are hints representing high-level abstractions that can be mapped to a specific back end resource manager. It is the responsibility of the EJB persistence machinery to ensure the necessary concurrency control, connection, and cache management when carrying out the persistence details. The EJB persistence manager can use access intent hints to make better performance decisions when carrying out its assigned task. A smaller number of access intents are hints to the EJB container, influencing the management of EJB collections.

Typically, you configure *bean level* access intent for your applications. You can also apply access intent policies to beans within the scope of *application profiles*. Consequently, you can configure beans with multiple and opposing access intent policies. The application profiling documentation explains in more detail how to configure an application to apply a particular access intent policy to a bean for one request, then apply another access intent policy to the same bean for a different request.

Support for applying access intent policies at the method level is deprecated in WebSphere Application Server Version 6.0. In this practice of configuring access intent, you apply a policy to methods within the scope of an EJB module so that the policy becomes the default access intent for all requests upon those methods.

## Access intent design considerations

**best-practices:** Refrain from over-tuning an application. You can introduce errors by incorrectly using the access intent service. For example, misuse of the wsPessimisticUpdate-NoCollision policy can result in lost updates; inappropriately setting the collection increment value can introduce performance issues; and problem determination is more difficult when an application is configured with multiple access intent policies.

**Note:** Clarity and simplicity should be your guiding principles when using the access intent service. This is even more important when applying access intent polices within the scope of application profiles.

Even though access intent policies can be configured on any method of an entity bean, some attributes of a policy can only be leveraged by the runtime environment under certain conditions. For example, concurrency and access intent are only used for CMP entity beans when the ejbLoad method is driven to open a connection and read data from a given resource; that data is cached and used to drive the proper queries during invocation of the ejbStore method. Read-ahead hints are only used during the execution of a finder for a bean. The collection increment and resource manager prefetch increment are only used on multi-object finders. Configuring policies on methods that do not use the policy is not an error. Only certain attributes of any policy are used, even when the policy is appropriately applied to a method. However, configuring policies unnecessarily throughout an application obscures the design of the application and complicates the maintenance of the application.

## Access intent with BMP entity beans

Access intent's declarative functionality provides great power to you as a CMP entity bean developer. You can provide hints on how the product should manage the details of persistence without having to explicitly manage any of the persistence logic in the application. There are situations, however, in which you might need to develop BMP entity beans. Since the only meaningful difference between BMP and CMP components is who provides the persistence logic, BMP entity beans should be able to leverage access intent hints just as the product does on behalf of CMP entity beans. BMP entity beans that use the access intent service participate in application profiling; that is, the value of the access intent attributes can differ from request to request, allowing the BMP entity bean to seamlessly modify its persistence strategy.

You can apply access intent policies to BMP entity bean methods as well as CMP entity bean methods. Because access intent hints are not contractual in nature, there is no obligation for a BMP entity bean to exploit them. BMP entity beans are expected to use only those access intent attributes that are important to that particular bean.

The current access intent policy is bound into the java:comp namespace for a particular BMP entity bean. That policy is current only for the duration of the method call during which the access intent policy was retrieved. In a typical scenario, you would cache the access type during invocation of the ejbLoad method so that appropriate actions can be taken during invocation of the ejbStore method.

## Access intent best practices

When applying access intent policies to EJB methods, consider the following issues.

- **Start by configuring the default access intent policy for an entity.** After your application is built and started, you can tune certain access paths in your application using application profiling or method-level access intent.
- **Don't mix access types.** Avoid using both pessimistic and optimistic policies in the same transaction. For most databases, pessimistic and optimistic policies use different isolation levels. This can result in multiple database connections, which prevents you from taking advantage of the performance benefits possible through connection sharing.

- **Take care when applying the `wsPessimisticUpdate-NoCollision` policy.** This policy does not ensure data integrity. No database locks are held, so concurrent transactions can overwrite each other's updates. Use this policy only if you can be sure that only one transaction attempts to update persistent store at any time.

For further information on Java Persistence API (JPA) Access intent, see the topic on JPA Access intent.

# Applying access intent policies to methods

You apply an access intent policy to a method, or set of methods, in an application's entity beans through the assembly tool.

## About this task

**Note:** Method-level access intent is deprecated in Version 6.0.

## Procedure

1. Start an assembly tool.
2. Optional: Open the Java EE perspective to work with Java EE projects. Click **Window > Open Perspective > Other > Java EE**.
3. Optional: Open the Project Explorer view. Click **Window > Show View > Project Explorer**. Another helpful view is the Navigator view (**Window > Show View > Navigator**).
4. Create a new application EAR file or edit an existing one.

   For example, to change attributes of an existing application, use the import wizard to import an EAR file. To start the import wizard:

   a. Select **File > Import > EAR file > Next**
   b. Select the EAR file.
   c. Create a WebSphere Application Server v6.0 type of Server Runtime. Select **New** to open the New Server Runtime Wizard and follow the instructions.
   d. In the *Target server* field, select *WebSphere Application Server v6.0* type of Server Runtime.
   e. Select **Finish**
5. In the Project Explorer view of the J2EE perspective, right-click the **Deployment Descriptor: EJB Module Name** under the EJB module for the bean instance, then select **Open With > Deployment Descriptor Editor**. A property dialog notebook for the EJB project is displayed in the property pane.
6. Select the **Access** tab.
7. On the right side of the **Access Intent for Entities 2.x (Method Level)** panel, select **Add**. The **Add Access Intent** panel displays.
8. Specify the **Name** for your new intent policy.
9. Select the **Access intent name** from the drop-down list.
10. Enter a **Description** to help you remember what this policy does.
11. Optional: Select **Read Ahead Hint**. A single access intent read ahead hint might not refer to the same bean type in more than one relationship. For example, if a **Department** enterprise bean has a relationship *employees* with the **Employee** enterprise bean, and also has a relationship *manager* with the **Employee** enterprise bean, then a read ahead hint cannot specify both *employees* and *manager*.
12. Click **Next**. The next **Add Access Intent** panel displays, with optional attributes.
13. Optional: Decide whether or not to overwrite these optional access intent attributes. Click on those you want to change.
14. Click **Next**. The next **Add Access Intent** panel, with a list of Enterprise Beans, displays.
15. Select one or more Enterprise Beans from the list.

    **Note:** If you selected **Read Ahead Hint** in an earlier step, you can only select **ONE** bean at this step.

16. Click **Next**. The next **Add Access Intent** panel, with a list of methods, displays.
17. Select the methods you want to use.
18. If you *DID NOT* select **Read Ahead Hint** in an earlier step, click **Finish**. If you *DID* select the Read Ahead Hint option, you can click **Next** to specify your Read Ahead Hint for the specified bean. The next **Add Access Intent** panel, with a list of EJB preload paths, displays.
19. Edit the EJB preload path by selecting relationship roles from the **Relationship roles:** window.
20. Click **Finish**. A new entry is created in the **Access Intent for Entities 2.x (Method Level)** panel

# Developing applications that use the Java Persistence API

## Developing JPA 2.x applications for a Java EE environment

Containers in the application server can provide many of the necessary functions for the Java Persistence API (JPA) in a Java Enterprise Edition (Java EE) environment. The application server also provides JPA command tools to assist you with developing applications in a Java EE environment.

### About this task

**Attention:** When you use these JPA command tools, run them from the <*profile_root*>/bin directory, rather than from the *app_server_root*/bin directory to make sure that you have the latest version of the commands for your release level.

For this task, you must specify the `com.ibm.ws.jpa.thinclient_8.0.0.jar` stand-alone Java archive (JAR) file in your class path. This stand-alone JAR file is available from the installation images. The location of this file on the server installation image is ${*app_server_root*}/runtimes/ `com.ibm.ws.jpa.thinclient_8.0.0.jar`..

**Important:** JPA applications require different configuration techniques from applications that use container-managed persistence (CMP) or bean-managed persistence (BMP). They do not follow the typical deployment techniques that are associated with applications that implement CMP or BMP. In JPA applications, you must define a persistence unit and configure the appropriate properties to ensure that the applications can run in a Java EE environment.

The container supports all necessary injections to ensure that applications run in the Java EE environment. For example, the container can inject the @PersistenceUnit and @PersistenceContext for your applications.

### Procedure

1. Generate your entities classes. These are Plain Old Java Object (POJO) entities. Depending upon your development model, you might use some or all of the JPA tools:
   - **Top-down mapping:** You start from scratch with the entity definitions and the object-relational mappings, and then you derive the database schemas from that data. If you use this approach, you are most likely concerned with creating the architecture of your object model and then writing your entity classes. These entity classes would eventually drive the creation of your database model. If you are using a top-down mapping of the object model to the relational model, develop the entity classes and then use OpenJPA functionality to generate the database tables that are based on the entity classes. The wsmapping tool helps with this approach.
   - **Bottom-up mapping:** You start with your data model, which are the database schemas, and then you work upwards to your entity classes. The wsreversemapping tool helps with this approach.
   - **Meet in the middle mapping:** probably the most common development model. You have a combination of the data model and the object model partially complete. Depending on the goals and requirements, you must negotiate the relationships to resolve any differences. Both the wsmapping tool and the wsreversemapping tool help with this approach.

The JPA solution for the application server provides several tools that help with developing JPA applications. Combining these tools with IBM Rational Application Developer provides a solid development environment for either Java EE or Java SE applications. Rational Application Developer includes GUI tools to insert annotations, a customized `persistence.xml` file editor, a database explorer, and other features. Another alternative is the Eclipse Dali project. More information about Rational Application Developer or the Eclipse Dali plug-in can be found at their respective websites.

2. Compile the entity classes.

   Compile the entities as you would any Java class, unless you are using the Criteria API. If you are using the Criteria API, you must also generate the Criteria API metamodel classes by including the following option with the javac command:

   ```
   -Aopenjpa.metamodel=true
   ```

   **Examples**

   The following are examples of how you use this option.

   For Linux, UNIX and z/OS platforms:

   ```
   app_server_root/java/bin/javac
   -Aopenjpa.metamodel=true
   -classpath app_server_root/runtimes/com.ibm.ws.jpa.thinclient_8.0.0.jar
   mypackage/MyEntity.java
   ```

   For Windows platform:

   ```
   app_server_root\java\bin\javac
   -Aopenjpa.metamodel=true
   -classpath app_server_root\runtimes\com.ibm.ws.jpa.thinclient_8.0.0.jar
    mypackage\MyEntity.java
   ```

   Using the javac command and the J2EE server plug-in:

   For Linux, UNIX and z/OS platforms:

   ```
   app_server_root/java/bin/javac
   -Aopenjpa.metamodel=true
   -classpath app_server_root/plugins/javax.j2ee.persistence.jar
   mypackage/MyEntity.java
   ```

   For Windows platform:

   ```
   app_server_root\java\bin\javac
   -Aopenjpa.metamodel=true
   -classpath app_server_root\plugins\javax.j2ee.persistence.jar
   mypackage\MyEntity.java
   ```

   For more information about using Criteria API and AnnotationProcessor6, refer to the Apache OpenJPA User Guide, Chapter 11: JPA Criteria and Chapter 4: Generation of Canonical Metamodel classes for AnnotationProcessor6 options and the information center topic, Criteria API.

3. Enhance the entity classes using the JPA enhancer tool, wsenhancer, for the application server. An enhancer is a tool that automatically adds code to your persistent classes after you have written them. The enhancer post-processes the bytecode that is generated by the Java compiler and adds the fields and methods that are necessary to implement the persistence features. Although JPA for the application server and OpenJPA can automatically enhance the entities at run time, you obtain better performance if you can enhance your entities when you build the application. The application does not attempt to enhance entities that are already enhanced.

   For examples of how to use the wsenhancer tool, see the topic, wsenhancer command.

4. Optional: If you are not using the development model for bottom-up mapping, generate or update your database tables automatically or by using the wsmapping tool.

   - By default, the object-relational mapping does not occur automatically, but you can configure the application server to provide that mapping with the openjpa.jdbc.SynchronizeMappings property. This property can accelerate development by automatically ensuring that the database tables match the object model. To enable automatic mapping, include the following line in the `persistence.xml` file:

     ```
     <property name="openjpa.jdbc.SynchronizeMappings" value="buildSchema(ForeignKeys=true)"/>
     ```

**Note:** To enable automatic object-relational mapping at run time, all of your persistent classes must be listed in the Java .class file, mapping file, and Java archive (JAR) file elements in XML format.

- To manually update or generate your database tables, run the JPA mapping tool for the application server from the command line to create the tables in the database. For examples on how to run the wsmapping tool, see the topic, wsmapping command.

5. Optional: If you are using DB2 and want to use static Structured Query Language (SQL), run the wsdbgen command. In order to use the wsdbgen command, IBM Optim pureQuery Run time must be installed. The wsdbgen command creates the *persistence_unit_name*.pdqxml file under the same META-INF directory where your persistence.xml file is located. If you have multiple persistence units, the wsdbgen command must be run for each persistence unit.

   When multiple pdqxml files are referenced by an application, use the Merge utility to combine them into a single pdqxml file. Specify the combined pdqxml file as pureQueryXml property of pdqProperties. Refer to the Merge utility documentation in the IBM Integrated Data Management information center.

   For examples on how to run this command, see the topic, wsdbgen command.

6. Optional: If you are using application-managed identity, generate an application-managed identity class with the wsappid tool. When you use an application-managed identity, one or more of the fields must be an identity field. Use an identity class if your entity has multiple identity fields and at least one of the fields is related to another entity. The application-managed identity tool generates Java code that uses the identity class for any persistent type that implements application-managed identity.

   For examples on how to use the wsappid tool, see the topic wsappid command.

### Example

The following is an example of a persistence.xml file:

```
<?xml version="1.0" encoding="UTF-8"?>
<persistence xmlns="http://java.sun.com/xml/ns/persistence"
             xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" version="2.0"
             xsi:schemaLocation="http://java.sun.com/xml/ns/persistence
http://java.sun.com/xml/ns/persistence/persistence_2_0.xsd">

<persistence-unit name="TheWildZooPU" transaction-type="JTA">
        <jta-data-source>jdbc/DataSourceJNDI</jta-data-source>
        <!-- additional Mapping file, in addition to orm.xml>
        <mapping-file>META-INF/JPAorm.xml</mapping-file>

        <class>com.company.bean.jpa.PersistebleObjectImpl</class>
        <class>com.company.bean.jpa.Animal</class>
        <class>com.company.bean.jpa.Dog</class>
        <class>com.company.bean.jpa.Cat</class>

   <properties>
           <property name="openjpa.ConnectionFactoryProperties"
                     value="PrettyPrint=true, PrettyPrintLineLength=72"/>
           <property name="openjpa.jdbc.SynchronizeMappings"
                     value="buildSchema(ForeignKeys=true)"/>
        </properties>

     </persistence-unit>
</persistence>
```

### What to do next

For more information about the commands, classes or other OpenJPA information, refer to the Apache OpenJPA User Guide.

## Developing JPA 2.x applications for a Java SE environment

Prepare persistence applications to test outside of the application server container in a Java SE environment.

## About this task

**Attention:** When you use these JPA command tools, run them from the *profile_root*/`bin` directory, rather than from the *app_server_root*/`bin` directory to make sure that you have the latest version of the commands for your release level.

For this task, you must specify the `com.ibm.ws.jpa.thinclient_8.0.0.jar` stand-alone Java archive (JAR) file in your class path. This stand-alone JAR file is available from the installation images. The location of this file on the server installation image is ${*app_server_root*}/`runtimes/com.ibm.ws.jpa.thinclient_8.0.0.jar`..

**Important:** Java Persistence API (JPA) applications require different configuration techniques from applications that use container-managed persistence (CMP) or bean-managed persistence (BMP). They do not follow the typical deployment techniques that are associated with applications that implement CMP or BMP. In JPA applications, you must define a persistence unit and configure the appropriate properties in the `persistence.xml` file to ensure that the applications can run in a Java SE environment.

There are some considerations for running JPA applications in a Java SE environment:

- Resource injection is not available. You must configure these services specifically or programmatically.
- The life cycle of the EntityManagerFactory and EntityManager are managed by the application. Applications control the creation, manipulation, and deletion of these constructs programmatically.

## Procedure

1. Generate your entities classes.

   These are Plain Old Java Object (POJO) entities. Depending upon your development model, you might use some or all of the JPA tools:

   **Top-down mapping**
   You start from scratch with the entity definitions and the object-relational mappings, and then you derive the database schemas from that data. If you use this approach, you are most likely concerned with creating the architecture of your object model and then writing your entity classes. These entity classes would eventually drive the creation of your database model. If you are using a top-down mapping of the object model to the relational model, develop the entity classes and then use OpenJPA functionality to generate the database tables that are based on the entity classes. The wsmapping tool would help with this approach.

   **Bottom-up mapping**
   You start with your data model, which are the database schemas, and then you work upwards to your entity classes. The wsreversemapping tool would help with this approach.

   **Meet in the middle mapping**
   Probably the most common development model. You have a combination of the data model and the object model partially complete. Depending on the goals and requirements, you must negotiate the relationships to resolve any differences. Both the wsmapping tool and the wsreversemapping tool would help with this approach.

   The JPA solution for the application server provides several tools that help with developing JPA applications. Combining these tools with IBM Rational Application Developer provides a solid development environment for either Java EE or Java SE applications. Rational Application Developer includes GUI tools to insert annotations, a customized`persistence.xml` file editor, a database explorer, and other features. Another alternative is the Eclipse Dali project. More information about Rational Application Developer or the Eclipse Dali plug-in can be found at their respective websites.

2. Compile the entity classes.

   Compile the entities as you would any Java class, unless you are using the Criteria API. If you are using the Criteria API, you must also generate the Criteria API metamodel classes by including the following option with the javac command:

```
-Aopenjpa.metamodel=true
```

The following are examples of how you use this option.

AIX HP-UX Linux Solaris

```
app_server_root/java/bin/javac
-Aopenjpa.metamodel=true
-classpath app_server_root/runtimes/com.ibm.ws.jpa.thinclient_8.0.0.jar
mypackage/MyEntity.java
```

Windows

```
app_server_root\java\bin\javac
-Aopenjpa.metamodel=true
-classpath app_server_root\runtimes\com.ibm.ws.jpa.thinclient_8.0.0.jar
 mypackage\MyEntity.java
```

For more information about using Criteria API and AnnotationProcessor6, refer to the Apache OpenJPA User Guide, Chapter 11: JPA Criteria and Chapter 4: Generation of Canonical Metamodel classes for AnnotationProcessor6 options and the information center topic, Criteria API.

3. Enhance the entity classes using the JPA enhancer tool, or specify the Java agent to perform dynamic enhancement at run time.
   - Use the wsenhancer tool. The enhancer post-processes the bytecode that is generated by the Java compiler and adds the fields and methods that are necessary to implement the persistence features. For example examples on how to use the wsenhancer tool, see the topic, wsenhancer command.
   - You can specify the Java agent mechanism to perform the dynamic enhancement at run time. For example, type the following at the command prompt:

```
java -javaagent:${app_client_root}/runtimes/com.ibm.ws.jpa.thinclient_8.0.0.jar com.xyz.Main
```

   **Attention:** You can either run the wsenhancer tool or specify the javaagent command. You do not need to do both.

4. Optional: If you are not using the development model for bottom-up mapping, generate or update your database tables automatically or by using the wsmapping tool.
   - By default, the object-relational mapping does not occur automatically, but you can configure the application server to provide that mapping with the openjpa.jdbc.SynchronizeMappings property. This property can accelerate development by automatically ensuring that the database tables match the object model. To enable automatic mapping, include the following line in the `persistence.xml` file:

     ```
     <property name="openjpa.jdbc.SynchronizeMappings" value="buildSchema(ForeignKeys=true)"/>
     ```

     **Note:** To enable automatic object-relational mapping at run time, all of your persistent classes must be listed in the Java `.class` file, mapping file, and Java archive (JAR) file elements in XML format.
   - To manually update or generate your database tables, run the JPA mapping tool for the application server from the command line to create the tables in the database. For examples on how to run the wsmapping tool, see the topic, wsmapping command.
5. Optional: If you are using DB2 and want to use static Structured Query Language (SQL), run the wsdbgen command. In order to use the wsdbgen command, IBM Optim PureQuery Run time must be installed. The wsdbgen command creates the *persistence_unit_name*`.pdqxml` file under the same META-INF directory where your `persistence.xml` file is located. If you have multiple persistence units, the wsdbgen command must be run for each persistence unit.

   When multiple `pdqxml` files are referenced by an application, use the Merge utility to combine them into a single `pdqxml` file. Specify the combined `pdqxml` file as pureQueryXml property of pdqProperties. See the Merge utility documentation in the IBM Integrated Data Management information center.

   For examples on how to run this command, see the topic, wsdbgen command.
6. Optional: If you are using application-managed identity, generate an application-managed identity class with the wsappid tool. When you use an application-managed identity, one or more of the fields must

be an identity field. Use an identity class if your entity has multiple identity fields and at least one of the fields is related to another entity. The application-managed identity tool generates Java code that uses the identity class for any persistent type that implements application-managed identity.

For examples on how to use the wsappid tool, see the topic wsappid command.

### Example

The following is a sample `persistence.xml` file for the Java SE Environment:

```
<?xml version="1.0" encoding="UTF-8"?>
<persistence xmlns="http://java.sun.com/xml/ns/persistence"
             xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" version="2.0"
             xsi:schemaLocation="http://java.sun.com/xml/ns/persistence
                 http://java.sun.com/xml/ns/persistence/persistence_2_0.xsd">

    <persistence-unit name="TheWildZooPU" transaction-type="RESOURCE_LOCAL">

        <!-- additional Mapping file, in addition to orm.xml>
        <mapping-file>META-INF/JPAorm.xml</mapping-file>

        <class>com.company.bean.jpa.PersistebleObjectImpl</class>
        <class>com.company.bean.jpa.Animal</class>
        <class>com.company.bean.jpa.Dog</class>
        <class>com.company.bean.jpa.Cat</class>

        <properties>
            <property name="openjpa.ConnectionDriverName"
                      value="org.apache.derby.jdbc.EmbeddedDriver" />
            <property name="openjpa.ConnectionURL"
                      value="jdbc:derby:target/database/jpa-test-database;create=true" />
            <property name="openjpa.Log"
                      value="DefaultLevel=INFO,SQL=TRACE,File=./dist/jpaEnhancerLog.log,Runtime=INFO,Tool=INFO" />
            <property name="openjpa.ConnectionFactoryProperties"
                      value="PrettyPrint=true, PrettyPrintLineLength=72" />
            <property name="openjpa.jdbc.SynchronizeMappings"
                      value="buildSchema(ForeignKeys=true)" />
            <property name="openjpa.ConnectionUserName"
                      value="user" />
            <property name="openjpa.ConnectionPassword"
                      value="password"/>
        </properties>

     </persistence-unit>

</persistence>
```

### What to do next

For more information about any of the commands, classes or other OpenJPA information, refer to the Apache OpenJPA User Guide.

## Bean validation in JPA

Data validation is a common task that occurs in all layers of an application, including persistence. The Java Persistence API (JPA) 2.0 provides support for the Bean Validation API so that data validation can be done at run time. This topic includes a usage scenario where bean validation is used in the JPA environment of a sample digital image gallery application.

The Bean Validation API provides seamless validation across technologies on Java Enterprise Edition 6 (Java EE 6) and Java Platform, Standard Edition (JSE) environments. In addition to JPA 2.0, these technologies include JavaServer Faces (JSF) 2.0 and Java EE Connector Architecture (JCA) 1.6. You can read more about bean validation in the topic, Bean Validation API.

There are three core concepts of bean validation: constraints, constraint violation handling, and the validator. If you are running applications in an integrated environment like JPA, there is no need to interface directly with the validator.

Validation constraints are annotations or XML code that are added to a class, field, or method of a JavaBeans component. Constraints can be built in or user-defined. They are used to define regular constraint definitions and for composing constraints. The built-in constraints are defined by the bean validation specification and are available with every validation provider. For a list of built-in constraints, see the topic, Bean validation built-in constraints. If you need a constraint different from the built-in constraints, you can build your own user-defined constraint.

## Constraints and JPA

The following usage scenario illustrates how a built-in constraint is used in the JPA architecture of a sample digital image gallery application.

In the first code example, a built-in constraint is added to a simple entity of the JPA model called *image*. An image has an ID, image type, file name, and image data. The image type must be specified and the image file name must include a valid JPEG or GIF extension. The code shows the annotated image entity with some built-in bean validation constraints applied.

```
package org.apache.openjpa.example.gallery.model;

import javax.persistence.Entity;
import javax.persistence.EnumType;
import javax.persistence.Enumerated;
import javax.persistence.GeneratedValue;
import javax.persistence.Id;
import javax.validation.constraints.NotNull;
import javax.validation.constraints.Pattern;

@Entity
public class Image {

    private long id;
    private ImageType type;
    private String fileName;
    private byte[] data;

    @Id
    @GeneratedValue
    public long getId() {
        return id;
    }

    public void setId(long id) {
        this.id = id;
    }

    @NotNull(message="Image type must be specified.")
    @Enumerated(EnumType.STRING)
    public ImageType getType() {
        return type;
    }

    public void setType(ImageType type) {
        this.type = type;
    }

    @Pattern(regexp = ".*\\.jpg|.*\\.jpeg|.*\\.gif",
        message="Only images of type JPEG or GIF are supported.")
    public String getFileName() {
        return fileName;
    }
```

```
    public void setFileName(String fileName) {
        this.fileName = fileName;
    }

    public byte[] getData() {
        return data;
    }

    public void setData(byte[] data) {
        this.data = data;
    }
}
```

The Image class uses two built-in constraints, @NotNull and @Pattern. The @NotNull constraint ensures that an ImageType element is specified and the @Pattern constraint uses regular expression pattern matching to ensure that the image file name is suffixed with a supported image format. Each constraint has corresponding validation logic that gets started at run time when the image entity is validated. If either constraint is not met, the JPA provider throws a ConstraintViolationException with the defined message. The JSR-303 specification also makes provisions for the use of a variable within the message attribute. The variable references a keyed message in a resource bundle. The resource bundle supports environment-specific messages and globalization, translation, and multicultural support of messages.

You can create your own custom validator and constraints. In the previous example, the Image entity used the @Pattern constraint to validate the file name of the image. However, it did not check constraints on the actual image data itself. You can use a pattern-based constraint; however, you do not have the flexibility that you would if you created a constraint specifically for checking constraints on the data. In this case you can build a custom method-level constraint annotation. The following is a custom or user-defined constraint called ImageContent.

```
package org.apache.openjpa.example.gallery.constraint;

import java.lang.annotation.Documented;
import java.lang.annotation.Retention;
import java.lang.annotation.Target;
import static java.lang.annotation.ElementType.METHOD;
import static java.lang.annotation.ElementType.FIELD;
import static java.lang.annotation.RetentionPolicy.RUNTIME;

import javax.validation.Constraint;
import javax.validation.Payload;

import org.apache.openjpa.example.gallery.model.ImageType;

@Documented
@Constraint(validatedBy = ImageContentValidator.class)
@Target({ METHOD, FIELD })
@Retention(RUNTIME)
public @interface ImageContent {
     String message() default "Image data is not a supported format.";
     Class<?>[] groups() default {};
  Class<? extends Payload>[] payload() default {};
  ImageType[] value() default { ImageType.GIF, ImageType.JPEG };
}
```

Next, you must create the validator class, ImageContentValidator. The logic within this validator gets implemented by the validation provider when the constraint is validated. The validator class is bound to the constraint annotation through the validatedBy attribute on the @Constraint annotation as shown in the following code:

```
package org.apache.openjpa.example.gallery.constraint;
import java.util.Arrays;
import java.util.List;
import javax.validation.ConstraintValidator;
```

```
import javax.validation.ConstraintValidatorContext;
import org.apache.openjpa.example.gallery.model.ImageType;
/**
 * Simple check that file format is of a supported type
 */
public class ImageContentValidator implements ConstraintValidator<ImageContent, byte[]> {
    private List<ImageType> allowedTypes = null;
    /**
     * Configure the constraint validator based on the image
     * types it should support.
     * @param constraint the constraint definition
     */
    public void initialize(ImageContent constraint) {
        allowedTypes = Arrays.asList(constraint.value());
    }
    /**
     *Validate a specified value.
     */
    public boolean isValid(byte[] value, ConstraintValidatorContext context) {
        if (value == null) {
            return false;
        }
        // Verify the GIF header is either GIF87 or GIF89
        if (allowedTypes.contains(ImageType.GIF)) {
            String gifHeader = new String(value, 0, 6);
            if (value.length >= 6 &&
                (gifHeader.equalsIgnoreCase("GIF87a") ||
                 gifHeader.equalsIgnoreCase("GIF89a"))) {
                return true;
            }
        }
        // Verify the JPEG begins with SOI and ends with EOI
        if (allowedTypes.contains(ImageType.JPEG)) {
            if (value.length >= 4 &&
                value[0] == 0xff && value[1] == 0xd8 &&
                value[value.length - 2] == 0xff && value[value.length -1] == 0xd9) {
                return true;
            }
        }
        // Unknown file format
        return false;
    }
}
```

Apply this new constraint to the getData() method on the Image class; for example:

```
@ImageContent
    public byte[] getData() {
        return data;
    }
```

When validation of the data attribute occurs, the isValid() method in the ImageContentValidator is started. This method contains logic for performing simple validation of the format of the binary image data. A potentially overlooked feature in the ImageContentValidator is that it can also validate for a specific image type. By definition, it accepts JPEG or GIF formats, but it can also validate for a specific format. For example, by changing the annotation to the following code example, the validator is instructed to only permit image data with valid JPEG content:

```
@ImageContent(ImageType.JPEG)
    public byte[] getData() {
        return data;
    }
```

*Type-level* constraints are also a consideration because you might need to validate combinations of attributes on an entity. In the previous examples validation constraints were used on individual attributes. Type-level constraints make it possible to provide collective validation. For example, the constraints

applied to the image entity validate that an image type is set (not null), the extension on the image file name is of a supported type, and the data format is correct for the indicated type. But, for example, it does not collectively validate that a file named `img0.gif` is of type GIF and the format of the data is for a valid GIF file image. For more information about type-level constraints, see the white paper, OpenJPA Bean Validation Primer, and the section "Type-level constraints."

## Validation groups

Bean validation uses validation groups to determine what type of validation and when validation occurs.

There are no special interfaces to implement or annotations to apply to create a validation group. A validation group is denoted by a class definition.

**Note:** When using groups, use simple interfaces. Using a simple interface makes validation groups more usable in multiple environments. Whereas, if a class or entity definition is used as a validation group, it might pollute the object model of another application by bringing in domain classes and logic that do no make sense for the application. By default, if a validation group or multiple groups is not specified on an individual constraint, it is validated using the javax.validation.groups.Default group. Creating a custom group is as simple as creating a new interface definition.

For more information about validation groups, read the white paper, OpenJPA Bean Validation Primer, and the section "Validation groups."

## JPA domain model

In addition to the Image entity are Album, Creator and Location persistent types. An Album entity contains a reference to collection of its Image entities. The Creator entity contains a reference to the album entities that the image Creator contributed to and a reference to the Image entities created. This provides full navigational capabilities to and from each of the entities in the domain. An embeddable location, has been added to image to support storing location information with the image.

The Album and Creator entities have standard built-in constraints. The embeddable location is more unique in that it demonstrates the use of the @Valid annotation to validate embedded objects. To embed location into an image, a new field and corresponding persistent properties are added to the Image class; for example:

```
private Location location;

    @Valid
    @Embedded
    public Location getLocation() {
        return location;
    }

    public void setLocation(Location location) {
        this.location = location;
    }
```

The @Valid annotation provides chained validation of embeddable objects within a JPA environment. Therefore, when image is validated, any constraints on the location it references are also validated. If @Valid is not specified, the location is not validated. In a JPA environment, chained validation through @Valid is only available for embeddable objects. Referenced entities and collections of entities are validated separately to prevent circular validation.

## Bean validation and the JPA environment

The JPA 2.0 specification makes integration with the Bean Validation API simple. In a JSE environment, bean validation is enabled by default when you provide the Bean Validation API and a bean validation

provider on your runtime class path. In a Java EE 6 environment, the application server includes a bean validation provider so there is no need to bundle one with your application. In both environments, you must use a Version 2.0 `persistence.xml` file.

A Version 1.0 `persistence.xml` provides no means to configure bean validation. Requiring a Version 2.0 `persistence.xml` prevents a pure JPA 1.0 application from incurring the validation startup and runtime costs. This is important given that there is no standard means for a 1.0-based application to disable validation. In a Java EE 6 environment, enable validation in an existing 1.0 application by modifying the root element of your `persistence.xml` file. The following example represents the `persistence.xml` file:

```
<?xml version="1.0" encoding="UTF-8"?>
<persistence xmlns="http://java.sun.com/xml/ns/persistence"
    xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xsi:schemaLocation="http://java.sun.com/xml/ns/persistence
    http://java.sun.com/xml/ns/persistence/persistence_2_0.xsd"
    version="2.0" >
...
</persistence>
```

### Validation modes

Bean validation provides three modes of operation within the JPA environment:

- Auto

  Enables bean validation if a validation provider is available within the class path. Auto is the default.
- Callback

  When callback mode is specified, a bean validation provider must be available for use by the JPA provider. If not, the JPA provider throws an exception upon instantiation of a new JPA entity manager factory.
- None

  Disables bean validation for a particular persistence unit.

Auto mode simplifies deployment, but can lead to problems if validation does not take place because of a configuration problem.

**Note:** Use either none or callback mode explicitly for consistent behavior.
Also, if none is specified, JPA optimizes at startup and does not attempt to perform unexpected validation. Explicitly disabling validation is especially important in a Java EE 6 environment where the container is mandated to provide a validation provider. Therefore, unless specified, a JPA 2.0 application started in a container has validation enabled. This process adds additional processing during life cycle events.

There are two ways to configure validation modes in JPA 2.0. The simplest way is to add a validation-mode element to the `persistence.xml` with the wanted validation mode as shown in the following example:

```
 <persistence-unit name="auto-validation">
          ...
    <!-- Validation modes: AUTO, CALLBACK, NONE -->
    <validation-mode>AUTO</validation-mode>
    ...
  </persistence-unit>
```

The other way is to configure the validation mode programmatically by specifying the javax.persistence.validation.mode property with value auto, callback, or none when creating a new JPA entity manager factory as shown in the following example:

```
Map<String, String> props = new HashMap<String, String>();
  props.put("javax.persistence.validation.mode", "callback");
        EntityManagerFactory emf =
            Persistence.createEntityManagerFactory("validation", props);
```

### Validation in the JPA life cycle

Bean validation within JPA occurs during JPA life cycle event processing. If enabled, validation occurs at the final stage of the PrePersist, PreUpdate, and PreRemove life cycle events. Validation occurs only after all user-defined life cycle events, since some of those events can modify the entity that is being validated. By default, JPA enables validation for the default validation group for PrePersist and PreUpdate life cycle events. If you must validate other validation groups or enable validation for the PreRemove event, you can specify the validation groups to validate each life cycle event in the `persistence.xml` as shown in the following example:

```
<persistence-unit name="non-default-validation-groups">
  <class>my.Entity</class>
  <validation-mode>CALLBACK</validation-mode>
  <properties>
   <property name="javax.persistence.validation.group.pre-persist"
       value="org.apache.openjpa.example.gallery.constraint.SequencedImageGroup"/>
   <property name="javax.persistence.validation.group.pre-update"
       value="org.apache.openjpa.example.gallery.constraint.SequencedImageGroup"/>
   <property name="javax.persistence.validation.group.pre-remove"
       value="javax.validation.groups.Default"/>
  </property>
 </persistence-unit>
```

The following example shows various stages of the JPA life cycle, including persist, update, and remove:

```
EntityManagerFactory emf =
           Persistence.createEntityManagerFactory("BeanValidation");
        EntityManager em = emf.createEntityManager();

        Location loc = new Location();
        loc.setCity("Rochester");
        loc.setState("MN");
        loc.setZipCode("55901");
        loc.setCountry("USA");

        // Create an Image with non-matching type and file extension
        Image img = new Image();
        img.setType(ImageType.JPEG);
        img.setFileName("Winter_01.gif");
        loadImage(img);
        img.setLocation(loc);

        // *** PERSIST ***
        try {
            em.getTransaction().begin();
            // Persist the entity with non-matching extension and type
            em.persist(img);
        } catch (ConstraintViolationException cve) {
            // Transaction was marked for rollback, roll it back and
            // start a new one
            em.getTransaction().rollback();
            em.getTransaction().begin();
            // Fix the file type and re-try the persist.
            img.setType(ImageType.GIF);
            em.persist(img);
            em.getTransaction().commit();
        }

        // *** UPDATE ***
        try {
            em.getTransaction().begin();
            // Modify the file name to a non-matching file name
            // and commit to trigger an update
            img.setFileName("Winter_01.jpg");
            em.getTransaction().commit();
        }  catch (ConstraintViolationException cve) {
```

```
            // Handle the exception.  The commit failed so the transaction
            // was already rolled back.
            handleConstraintViolation(cve);
        }
        // The update failure caused img to be detached. It must be merged back
        // into the persistence context.
        img = em.merge(img);

        // *** REMOVE ***
        em.getTransaction().begin();
        try {
            // Remove the type and commit to trigger removal
            img.setType(ImageType.GIF);
            em.remove(img);
        }  catch (ConstraintViolationException cve) {
            // Rollback the active transaction and handle the exception
            em.getTransaction().rollback();
            handleConstraintViolation(cve);
        }
        em.close();
        emf.close();
```

## Exceptions

Validation errors can occur in any part of JPA life cycle.

If one or more constraints fail to validate during a life cycle event, a ConstraintViolationException is thrown by the JPA provider. The ConstraintViolationException thrown by the JPA provider includes a set of ConstraintViolations that occurred. Individual constraint violations contain information regarding the constraint, including: a message, the root bean or JPA entity, the leaf bean which is useful when validating JPA embeddable objects, the attribute which failed to validate, and the value that caused the failure. The following is a sample exception handling routine:

```
private void handleConstraintViolation(ConstraintViolationException cve) {
      Set<ConstraintViolation<?>> cvs = cve.getConstraintViolations();
   for (ConstraintViolation<?> cv : cvs) {
     System.out.println("------------------------------------------------");
           System.out.println("Violation: " + cv.getMessage());
           System.out.println("Entity: " + cv.getRootBeanClass().getSimpleName());
           // The violation occurred on a leaf bean (embeddable)
           if (cv.getLeafBean() != null && cv.getRootBean() != cv.getLeafBean()) {
              System.out.println("Embeddable: " +
cv.getLeafBean().getClass().getSimpleName());
           }
           System.out.println("Attribute: " + cv.getPropertyPath());
           System.out.println("Invalid value: " + cv.getInvalidValue());
      }
    }
```

Constraint violation processing is typically simple when using attribute-level constraints. If you are using a type-level validator with type-level constraints, it can be more difficult to determine which attribute or combination of attributes failed to validate. Also, the entire object is returned as the invalid value instead of an individual attribute. In cases where specific failure information is required, use of an attribute-level constraint or a custom constraint violation might be provided as described in the Bean Validation specification.

## Sample

The JPA model and image gallery application usage scenario provided in this topic can be implemented through a sample that is provided in the white paper, OpenJPA Bean Validation primer.

## wsjpa properties

The extension properties of Java Persistence API (JPA) for WebSphere Application Server can be specified with the openjpa or wsjpa prefix. This topic features the wsjpa properties.

### wsjpa.AccessIntent

Use this property to define a TaskName that in the `persistence.xml` file using the wsjpa.AccessIntent property name in a persistence unit. The property value is a list of TaskNames, entity types and access intent definitions.

For more information and examples on how the wsjpa.AccessIntent property is used, see the topic Specifying TaskName in a JPA persistence unit.

### wsjpa.jdbc.Schema

Specifies the schema name in a DB2 package collection when using multiple DB2 package collections.

For more information about using the wsjpa.jdbc.Schema property see the topic, Configuring pureQuery to use multiple DB2 package collections.

### wsjpa.jdbc.CollectionId

Specifies the collection Id name in a DB2 package collection when using multiple DB2 package collections.

For more information about using the wsjpa.jdbc.CollectionId property see the topics, Configuring pureQuery to use multiple DB2 package collections and Configuring data source JDBC providers to use pureQuery in a Java SE environment.

## Criteria API

The Criteria API is an API for building queries with Java objects, as an alternative to building strings for Java Persistence Query Language (JPQL) queries.

The Criteria API supports building queries dynamically at run time, and also the ability to build type-safe queries that can be verified by the compiler. The correctness of JPQL queries cannot be verified by the compiler, and must be verified at run time during testing.

The following is a sample JPQL query that returns a list of employees with less than five years of service:

```
SELECT e FROM Employee e WHERE e.serviceyears < 5
```

Here is a sample of the equivalent Criteria query:

```
QueryBuilder qb = emf.getQueryBuilder();
CriteriaQuery q = qb.create(Employee.class);
Root e = q.from(Employee.class);
q.where(qb.lt(e.get(Employee_.serviceyears), 5));
TypedQuery tq = em.createQuery(q);
List result = q.getResultList();
```

**Note:** `Employee_` is the Metamodel of the Employee class.

Two important features are improvements from JPQL:

- The Criteria API can express queries that are not possible through JPQL. For more detailed information see the section, "Editable data store expressions", in the developerWorks article, Dynamic, typesafe queries in JPA 2.0.
- A CriteriaQuery can be edited programmatically. For more information see the section, "Editable query", in the developerWorks article, Dynamic, typesafe queries in JPA 2.0.

You can read more about the Criteria API in the Apache OpenJPA User Guide.

# wsappid command

The Java Persistence API (JPA) specification supports an entity primary key to be made up of more than one column. In this case, the primary key is called a *composite* or *compound* primary key. Provide an ID class, which is specified by the @IdClass annotation, to manage a composite primary key. Use the identity tool for JPA to generate an ID class for entities that use composite primary keys.

## Syntax

Before running the command, you must have a copy of the `persistence.xml` file on the classpath, or specify it as a properties file in the -p [*path_to_persistence.xml*] argument. Issue the command from the `bin` subdirectory of the *profile_root* directory.

The command syntax is as follows:

```
wsappid.sh [parameters][arguments]
```

```
wsappid.bat [parameters][arguments]
```

## Parameters

The wsappid tool accepts the standard set of command-line arguments that are defined by the configuration framework along with the following:

- **-directory/-d** *<output_directory>*: The path to the output directory.

  If the directory does not match the generated output ID class package, the package structure is created beneath the directory. If this parameter is not specified, the wsappid tool attempts to find the directory of the `.java` file for the class that supports persistence. If a `.java` file is not found, the wsappid tool uses the current directory.
- **-ignoreErrors/-i** <true/t | false/f>: If this parameter is set to `false`, an exception is occurs when the tool is run on any class that does not use the application identity. An error also occurs if any class does not have the base class in the inheritance hierarchy.
- **-token/-t** *<token>*: The token that is used to separate the values of strung primary keys in the string form of the object ID.

  Use this option only if there are multiple primary key fields. The default is `"::"`.
- **-name/-n** *<id_class_name>*: The name of the identity class to generate.

  If this option is specified, the wsappid tool must run on exactly one class. If the class metadata already names an ID class for the object, this option is ignored. If the name is not fully qualified, the package of the persistence class is appended to form the fully qualified name.
- **suffix** *<id_class_suffix>*: A string with which to suffix each persistent class name to form the identity class name.

  This option is overridden by the **-name/-n** parameter or by any object ID class that is specified in the metadata.

Each additional argument to the wsappid tool must be one of the following:

- The full name of a persistent class.
- The `.java` name for a persistent class.
- The `.class` file of a persistent class.

## Usage

The identity tool used with JPA for application server simplifies the task of creating an identity class for entities that use composite IDs. A composite ID is an identity with more than one field as its primary key. The entity class must be compiled, and primary keys must be identified in the entity class. Run the wsappid tool from the command line in the *profile_root*/bin/ directory. When you run this command, a new

class representing the composite ID of the entity is generated. Messages and errors are logged to the console as specified.

### Examples

Consider the following entity:

```
@Entity
public class Employee {

@Id
private int division;

@Id private int id;
// . . .
}
```

Before the entity is used, an ID class is needed. For this example, assume that the entity is found in the `src/main/java` directory.

To generate an ID class for the Magazine entity run the following:

AIX HP-UX Linux Solaris

```
wsappid.sh -s Id src/main/java/Employee.java -d src/main/java
```

Windows

```
wsappid.bat -s Id src\main\java\Employee.java -d src\main\java
```

A new class, EmployeeId.java, is generated in the `src/main/java` directory.

### Additional information

Read the Application identity tool in persistence classes information in the Apache OpenJPA User Guide for more information.

## wsenhancer command

The entity enhancer tool for Java Persistence API (JPA) applications inserts bytecode into an entity class file that supports the JPA provider to manage the state of an entity.

JPA with the application server requires that all entity classes be enhanced if you want to manage their state. In a container-managed environment, automated enhancement is provided by the containers. In a Java SE environment, though, there are no containers to manage persistence and you might use this command frequently before packaging application files for testing. After you have created the JPA entities, you can run the wsenhancer tool to inject bytecode into the entities before packaging the Java archive (JAR) file into the enterprise archive (EAR) file for the application.

### Syntax

Before running the command, you must have a copy of the `persistence.xml` file on the classpath, or specify it as a properties file in the -p [*path_to_persistence.xml*] argument. Issue the command from the `bin` subdirectory of the *profile_root* directory.

The command syntax is as follows:

AIX HP-UX Linux Solaris

```
wsenhancer.sh [parameters][arguments]
```

Windows

```
wsenhancer.bat [parameters][arguments]
```

## Parameters

The enhancer accepts the standard set of command-line arguments defined by the configuration framework along with the following:

- **-directory/-d** *<output directory>*: Specifies the path to the output directory.

  If the directory does not match the enhanced class package, the package structure is created beneath the directory. By default, the enhancer overwrites the original `.class` file.
- **-enforcePropertyRestrictions/-epr** <true/t | false/f>: Specifies whether to generate an exception when a property access entity is not obeying the restrictions that are placed on property access.

  The default is set to `false`.
- **-addDefaultConstructor/-adc** <true/t | false/f>: Specifies that all of the persistent classes define a no-argument constructor. This flag informs the enhancer to add a protected no-arg constructor to any persistent classes in which the constructor is not already present.
- **-tmpClassLoader/-tcl** <true/t | false/f>: Specifies whether the enhancer should load persistent classes with a temporary class loader.

  This function supports other code to load the enhanced version of the class afterward within the same Java virtual machine (JVM). The default is set to true.

  **Note:** If you are encountering class loading problems when running the enhancer, you can set this flag to `false` as a debugging step.
- For class name, specify one of the following:
  - The full name of a class.
  - The `.java` name for a class.
  - The `.class` file of a class.

If you do not provide arguments to the enhancer, it runs on the classes in your persistent class list.

## Usage

To use the wsenhancer tool you need entities defined to the JPA specifications, and the entities must be compiled. Run the wsenhancer tool against the entities before packaging them into a JAR file. If the entities are already packaged, you extract the entity class files, run the enhancer, and recreate the JAR file.

To enhance your entities:

- Verify that your entities are in the class path, if they are not, add them.
- Run the wsenhancer command. It is found in ${profile_root}/bin directory.

Messages and errors are logged to the administrative console as specified in the log settings. After starting the wsenhancer command, your files are enhanced.

## Examples

To enhance all entities on the class path:

AIX HP-UX Linux Solaris

```
$ cd build
/home/user/myproject/build $ ${profile_root}/bin/wsenhancer.sh
```

Windows

```
C:\myproject\cd build
C:\myproject\build>%profile_root%\bin\wsenhancer.bat
```

All entities in myproject are enhanced.

To enhance a specific entity when you have the source files:

AIX HP-UX Linux Solaris

```
$ cd build
/home/user/myproject/build $ ${profile_root}/bin/wsenhancer.sh Magazine.java
```

Windows

```
C:\myproject\cd build
C:\myproject\build>%profile_root%\bin\wsenhancer.bat Magazine.java
```

To enhance a specific entity when you have the compiled class files:

AIX HP-UX Linux Solaris

```
$ export CLASSPATH=target/classes
$ ${profile_root}/bin/wsenhancer.sh /bin/wsenhancer.sh target/classes/jpa/example/MyEntity.class
```

Windows

```
C:> cd build
C:\build> SET CLASSPATH=target\classes
C:\build>%profile_root%\bin\wsenhancer.bat \bin\wsenhancer.bat target\classes\jpa\example\Magazine.class
```

The entity, Magazine.java, located in project are enhanced.

### Additional information

For more information about enhancement tools, see the section on persistent classes in the Apache OpenJPA documentation.

## wsmapping command

The wsmapping tool is used to provide top-down mapping of the entity object model to the database relational model. You can use the wsmapping tool to create database tables.

### Syntax

Before running the command, you must have a copy of `persistence.xml` on the class path, or specify it as a properties file in the -p [*path_to_persistence.xml*] argument. Issue the command from the `bin` subdirectory of the *profile_root* directory.

The command syntax is as follows:

AIX HP-UX Linux Solaris

```
wsmapping.sh [options][arguments]
```

Windows

```
wsmapping.bat [options][arguments]
```

### Parameters

The mapping tool accepts the standard set of command-line arguments defined by the configuration framework with the following options:

- **-schemaAction/-sa** <add | refresh | drop | build | reflect | retain | createDB | import | export | none>: The action to implement against the schema.

These options correspond to the actions of the schema tool. **Add** is the default action if none is specified. Actions can be composed in a list separated by commas.

**Note:** The wsmapping tool accepts the -action/-a flag to specify the action to take on individual classes. Unless you are running wsmapping on all of your persistent types at once, or dropping a mapping, you must use the default **add** action or the **build** action. Otherwise, you might inadvertently drop schema components that are used by classes that you are not currently running the tool against.

- **-schemaFile/-sf** <true/t | false/f>: This option can be used to write the planned schema to an XML document rather than modify the database.

  The XML document can then be modified, manipulated and committed to the database with the schema tool.
- **-sqlFile/-sql** <stdout | output file>: This option can be used to write the planned schema modifications to an SQL script rather than modify the database.

  Combine this parameter with a **schemaAction** of build to generate a script that recreates the schema for the current mappings, even if the schema exists.
- **-dropTables/-dt** <true/t | false/f>: When this option is set to true, schema drops tables that appear to be unused during **retain** and **refresh** actions.

  The default is `true`.
- **-dropSequences/-dsq** <true/t | false/f>: If this option is set to `true`, schema drops sequences that are unused during **retain** and **refresh** actions.

  The default is `true`.
- **-openjpatables/-ot** <true/t | false/f>: When reflecting the schema, this parameter determines whether to reflect on tables and sequences with names that start with OPENJPA_.

  Certain OpenJPA components use these tables and sequences, such as the table schema factory. When using other actions, the openjpaTables parameter controls whether these tables can be dropped or not. The default setting is `false`.
- **-ignoreErrors/-i** <true/t | false/f>: If set to `false`, an exception is occurs if the tool encounters database errors.

  The default is set to `false`.
- **-schemas/-s** *<schema list>*: Denotes a list of schema and table names the OpenJPA should access when running the wsschema tool.

  This is the equivalent to setting the openjpa.jdbc.Schemas property to run once. This parameter corresponds to the **-schemas/-s** parameter in the wsschema tool. This option is ignored if **-readSchema/-rs** is not set to `true`.
- **-readSchema/-rs** <true/t | false/f>: Set this option to `true` to read the entire existing schema when the mapping tool runs.

  Reading the existing schema ensures that OpenJPA does not generate any mappings that use the table, index, primary key or foreign key names that conflict with existing names.

  **Note:** Depending on the particular JDBC driver, selecting the **-readSchema/-rs** function can slow down the process for large schemas.
- **-primaryKeys/-pk** <true/t | false/f>: This flag determines if the primary keys can be manipulated on existing tables.

  The default is `true`.
- **-foreignKeys/fk** <true/t | false/f>: This flag determines if foreign keys can be manipulated on existing tables.

  The default is `true`. This means that to add a new foreign key to a class that has already been mapped, you must explicitly set this parameter flag to `true`.
- **-indexes/-ix** <true/t | false/f>: This flag determines if indexes can be manipulated on existing tables.

  The default is `true`. This means that to add new indexes to a class that has already been mapped, you must explicitly set this parameter flag to `true`.
- **-sequences/-sq** <true/t | false/f>: This flag determines if sequences can be manipulated.

The default is `true`.
- **-meta/-m** <true/t | false/f>: This flag determines whether a mapping applies to metadata rather than, or in addition to, standard mappings.
- The wsmapping tool accepts the **-action/-a** flag to specify the action to take on each class. Multiple actions can be composed in a list, separated by commas. The available actions are:
  - **buildSchema**: This is the default action. The **buildSchema** action makes the database schema match your existing mappings. If the provided mappings conflict with the class definitions, OpenJPA fails with an informative exception.
  - **validate**: Ensure that the mappings for the given classes are valid and that they match the schema of the database. No mappings of tables are changed as a result of this action. An exception occurs if any mappings are invalid.

Each additional argument to the wsmapping tool must be one of the following:
- The full name of a persistent class.
- The `.java` name for a persistent class.
- The `.class` file of a persistent class.

If you do not supply any arguments to the wsmapping tool, it runs on the classes in the persistent classes list.

## Usage

Before running the wsmapping tool, you must configure the data source information, including the URL, user, and password. It is required that the wsenhancer tool is run before the wsmapping tool to insert bytecode into the entity classes. Also, the compiled class files for your entities should be on the class path. Assume that entity class files can be found in target/classes, for example:

AIX HP-UX Linux AIX HP-UX Solaris Solaris

```
export CLASSPATH=${CLASSPATH}:target/classes

wsmapping.sh ...
```

Windows

```
SET CLASSPATH=%CLASSPATH%;target\classes

wsmapping.bat . . .
```

To create tables, run the wsmapping command from the ${profile_root}/bin directory. When completed, the database tables are created or updated. Messages and errors are logged to the administrative console as specified by log settings.

wsmapping.sh . . . On Windows :

**Tip:** By specifying the buildSchema parameter to the openjpa.jdbc.SynchronizeMappings property, the mapping tool provides the default mapping that matches with the database schema automatically. You are not required to run this mapping tool if the default mapping satisfies the necessary database schema.

## Examples

To create the database tables needed for the `Magazine.java` file:

AIX HP-UX Linux Solaris

```
${profile_root}/bin/wsmapping.sh Magazine.java
```

Windows

```
${profile_root}\bin\wsmapping.sh Magazine.java
```

To drop the tables for `Magazine.java`:

AIX HP-UX Linux Solaris

```
C:\> %profile_root%/bin/wsmapping.sh -sa dropDB Magazine.java
```

Windows

```
C:\> %profile_root%\bin\wsmapping.bat -sa dropDB Magazine.java
```

To validate the mappings for all classes on the class path:

AIX HP-UX Linux Solaris

```
C:\> %profile_root%/bin/wsmapping.sh -a validate
```

Windows

```
C:\> %profile_root%\bin\wsmapping.bat -a validate
```

### Additional information

See the mapping information in the Apache OpenJPA User Guide for more information and examples.

## wsreversemapping command

The wsreversemapping tool generates persistent class definitions and metadata from a database schema.

### Syntax

Before running the command, you must have a copy of the `persistence.xml` file on the class path, or specify it as a properties file in the -p [*path_to_persistence.xml*] argument. Issue the command from the `bin` subdirectory of the *profile_root* directory.

The command syntax is as follows:

AIX HP-UX Linux Solaris

```
wsreversemapping.sh [parameters][arguments]
```

Windows

```
wsreversemapping.bat [parameters][arguments]
```

### Parameters

The wsreversemapping tool accepts the standard set of command-line arguments defined by the configuration framework along with the following:

- **-schemas/-s** *<schema and table names>*: A list of schema and table names, separated by commas, to run the wsreversmapping tool on if no XML schema file is supplied.

  Each element of the list must follow the naming conventions for the openjpa.jdbc.Schemas property. If this parameter flag is omitted, it defaults to the value of the **Schemas** property. If the **Schemas** property is not defined, then all schemas are reverse mapped.
- **-package/-p** *<package name>*: The package name of the generated classes.

  If no package name is given, the generated code does not contain package declarations.
- **-directory/-d** *<output directory>*: All generated code and metadata is written to the directory at this path.

  If the path does not match the package of a class, the package structure is created beneath this directory. This parameter defaults to the current directory.

- **-useSchemaName/-sn** <true/t | false/f>: Set this parameter flag to `true` to include the schema and the table name in the name of each generated class.

  This method can be useful when dealing with multiple schemas that have tables with identical names.
- **-useForeignKeyName/-fkn** <true/t | false/f>: Set this parameter flag to `true` if you want the field names for relations to be based on the database foreign key name.

  By default, relation field names are derived from the name of the related class.
- **-nullableAsObject/-no** <true/t | false/f>: By default, all non-foreign key columns are mapped to primitives.

  Set this parameter flag to `true` to generate primitive wrapper fields instead for columns that support null values.
- **-blobAsObject/-bo** <true/t | false/f>: By default, all binary columns are mapped to the byte[] fields.

  Set this parameter flag to `true` to map them to Object fields instead.

  **Attention:** When mapped this way, the column is presumed to contain a serialized Java object.
- **-primaryKeyOnJoin/pkj** <true/t | false/f>: The standard reverse mapping tool behavior is to map all tables with primary keys to persistent classes.

  If your schema has primary keys on many join tables as well, set this flag to `true` to avoid creating classes for those tables.
- **-inverseRelations/-ir** <true/t | false/f>: Set this parameter flag to `false` to prevent the creation of inverse one-to-many or one-to-one relations for every many-to-one or one-to-one relation detected.
- **-useDatastoreIdentity/-ds** <true/t | false/f>: Set to `true` to use data store identity for tables that have single numeric primary key columns.

  Typically, the tool uses application identity for all generated classes.
- **-useBuiltinIdentityClass/-bic** <true/t | false/f>: Set this parameter flag to `false` to prevent the wsreversemapping tool from using built-in application identity classes when possible.

  This forces the tool to create custom application identity classes even when there is only one primary key column.
- **-innerIdentityClasses/-inn** <true/t | false/f>: Set this parameter flag to `true` to have any generated application identity classed be created as static inner classes within the persistent classes.

  The default setting is `false`.
- **-identityClassSuffix/-is** *<suffix>*: Suffix to append to the class names to form application identity class names, or for inner identity classes, the inner class name.

  The default suffix is `Id`.
- **-typeMap/-typ** <type mapping>: A string that specifies the default Java classes to generate for each SQL type that is seen in the schema.

  The format is SQLTYPE1=JavaClass1, SQLTYPE2=JavaClass2. The SQL type name first looks for a customization that is based on SQLTYPE(SIZE,PRECISION), then SQLTYPE(SIZE), and then SQLTYPE. If a column with type CHAR is found, it first looks for the CHAR(50,0) type name specification, then it looks for the CHAR(50), and finally for the CHAR. For example, to generate a char array for every char column whose size is exactly 50 characters, and to generate a short for every type name of INTEGER, you might specify, CHAR(50)=char[],INTEGER=short.

  **Attention:** Various databases report different type names differently, one database type might not work for another database. Enable TRACE level logging on the metadata channel to track which type names JPA for WebSphere Application Server is examining.
- **-customizerClass/-cc** *<class name>*: The full class name of an org.apache.openjpa.jdbc.meta.ReverseCustomizer customization plug-in.

  If you do not specify a reverse customizer of your own, the system defaults to a PropertiesReverseCustomizer. This customizer supports specifying simple customization options in the properties file given with the -customizerProperties flag.
  - **-customizerProperties/-cp***<properties file or resource>*: The path or resource name of a properties file to pass to the reverse customizer on initialization.
  - **-customizer/-c** *<property name> <property value>*: The given property name is matched with the corresponding Java bean property in the specified reverse customizer, and set to the given value.

### Usage

The wsreversemapping tool is used to perform reverse (bottom-up) mappings of database tables to entity source files. This is useful if developers want to generate Java files from a database for use in other JPA applications. To run this tool:

- You must have database tables and your database connection configured.
- Run the wsreversemapping tool from the command line in the $ {profile_root}/bin directory.
- The tool generates `.java` files for every class, along with an XML descriptor file, `orm.xml`.

The generated Java files from the wsreversemapping tool might require some editing before they can be used in an application. Also, generated files do not contain annotations. Annotations can be added manually. Messages and errors are logged to the administrative console as specified by the configuration.

### Examples

Generate entities based on the information saved in the schema.xml file. Schema.xml was created by running the schema tool. The Java files are created in the **src** directory and use the package com.xyz:

AIX HP-UX Linux Solaris

```
${profile_root}/bin/wsreversemapping.sh -pkg com.xyz -d ./src schema.xml
```

Windows

```
${profile_root}\bin\wsreversemapping.bat -pkg com.xyz -d ./src schema.xml
```

Generate entities based on information in a DB2 database. Entities are created in the **src** directory, and use the package com.reversemapped:

AIX HP-UX Linux Solaris

```
C:\> %profile_root%/bin/wsreversemapping.bat -sa dropDB Magazine.javapkg com.reversemapped -d src
-connectionDriverName=com.ibm.db2.jcc.DB2Driver -connectionURL=jdbc:db2:localhost:50000/TEST
-connectionUser=db2User -connectionPassword=db2Password
```

Windows

```
C:\> %profile_root%\bin\wsreversemapping.bat -sa dropDB Magazine.javapkg com.reversemapped -d src
-connectionDriverName=com.ibm.db2.jcc.DB2Driver -connectionURL=jdbc:db2:localhost:50000/TEST
-connectionUser=db2User -connectionPassword=db2Password
```

### Additional information

For more information, read the mapping section in the Apache OpenJPA User Guide.

## wsschema command

The schema tool can be used to view the database schema in XML form or match an XML schema to an existing database.

The wsschema tool can reflect on the current database schema, optionally translating it into an XML representation for further manipulation. The schema tool can take an XML schema definition, calculate the differences between the XML and the existing database schema, and apply the necessary changes to make the databases correspond to the XML schema. The XML format used by the schema tool is abstract from the differences in SQL dialects used by different vendors. The tool also automatically adapts its SQL to meet foreign dependencies, thus the schema tool is useful as a general way to manipulate the schemas.

## Syntax

The command syntax is as follows:

AIX HP-UX Linux Solaris

```
wsschema.sh [parameters][arguments]
```

Windows

```
wsschema.bat [parameters][arguments]
```

Issue the command from the `bin` subdirectory of the *profile_root* directory.

## Parameters

The wsschema tool accepts the standard set of command-line arguments defined by the configuration framework along with the following:

- **-ignoreErrors/-i** <true/t | false/f>: If set to `false`, an exception occurs if the tool encounters any database errors.

  The default is set to `false`.
- **-file/-f** *<stdout | output file>*: Use this option to write a SQL script for the planned schema modifications, rather than committing them to the database.

  When used with the export or reflect actions, the named file is used to write the exported schema XML. If the file names a resource in the class path, data is written to that resource. Use stdout to write to standard output. The default setting is `stdout`.
- **-openjpatables/-ot** <true/t | false/f>: When reflecting the schema, this parameter determines whether to reflect on tables and sequences whose names start with OPENJPA_.

  Certain OpenJPA components can use such tables and sequences, like the table schema factory. When using other actions, openjpaTables controls if these tables can be dropped. The default setting is `false`.
- **-dropTables/-dt** <true/t | false/f>: When this option is set to `true`, schema drops tables that are unused during retain and refresh actions.

  The default is `true`.
- **-dropSequences/-dsq** <true/t | false/f>: If this option is set to `true`, schema drops sequences that are unused during retain and refresh actions.

  The default is `true`.
- **-sequences/-sq** <true/t | false/f>: This flag determines if sequences can be manipulated.

  The default is `true`.
- **-indexes/-ix** <true/t | false/f>: This flag determines if indexes can be manipulated on existing tables.

  The default is `true`.
- **-primaryKeys/-pk** <true/t | false/f>: This flag determines if primary keys can be manipulated on existing tables.

  The default is `true`.
- **-foreignKeys/fk** <true/t | false/f>: This flag determines if foreign keys can be manipulated on existing tables.

  The default is `true`.
- **-record/-r** <true/t | false/f>: This flag permits or prevents writing schema changes made by the schema tool to the current schema factory.

  Select `true` to permit writing schema changes or false to prevent writing schema changes. The default is set to `true`.
- **-schemas/-s** *<schema list>*: Denotes a list of schema and table names the OpenJPA should access when running the schema tool.

  This is the equivalent to setting the openjpa.jdbc.Schemas property to run one time.

**Important:** The schema tool accepts the **-action/-a** flag. Multiple actions can be composed in a list, separated by commas. The available actions are:

- **add**: This is the default action if no other actions are specified. It updated the schema with the given XML documents by adding tables, columns, indexes, or other components. This action never drops any schema components.
- **retain**: This action keeps all schema components in the given XML definition but drops the rest from the database. This action never adds any schema components.
- **drop**: Drops all schema components in the schema XML. This action drops tables only if they would have 0 columns after dropping all columns listed in the XML.
- **refresh**: This action is the equivalent of the **retain** and the **add** functions.
- **build**: Generates SQL to build a schema matching the one in the supplied XML file. Unlike the**add** action, this option does not take into account the fact that part of the schema defined in the XML file may already exist in the database. This action is typically used with the **-file/-f** parameter flag to write a SQL script. This script can be used later to recreate the schema in the XML.
- **reflect**: Generates an XML representation of the current database schema.
- **createDB**: This action generates SQL to recreate the current database. This action is typically used with the **-file/-f** parameter flag to write a SQL script that can be used to recreate the current schema on a new database.
- **dropDB**: Generates SQL to drop the current database. Like the **createDB** action, this can be used with the **-file/-f** parameter flag to script a database drop rather than manually perform it.
- **import**: Imports the given XML schema definition into the current schema factory.

  **Note:** This action does nothing if the schema factory does not store a record of the schema.
- **export**: Exports the current schema factory stored schema definition to an XML file.

  **Note:** This can produce an empty file if the schema factory does not store a record of the schema.
- **deleteTableContents**: This action implements SQL to delete all rows from all tables that OpenJPA finds.

## Usage

The wsschema tool is used to obtain an XML file that describes the schema of your database. To generate an XML schema file:

- You must have database tables and your database connection configured.
- Run the wsschema tool from the command line in the $ {profile_root}/bin directory.
- The tool generates an XML file that describes the database schema.

Messages and errors are logged to the administrative console as specified by the configuration.

## Examples

Add the necessary schema components to the database to match the given XML document without dropping any data:

AIX HP-UX Linux Solaris

```
$ wsschema.sh targetSchema.xml
```

Windows

```
$ wsschema.bat targetSchema.xml
```

Repeat the same action as the previous example, this time not changing the database but instead writing any planned changes to a SQL script:

AIX HP-UX Linux Solaris

```
wsschema.sh -f script.sql targetSchema.xml
```

Windows

```
wsschema.bat -f script.sql targetSchema.xml
```

Write an SQL script that recreates the current database:

AIX HP-UX Linux Solaris

```
$ wsschema.sh -a createDB -f script.sql
```

Windows

```
$ wsschema.bat -a createDB -f script.sql
```

Refresh the schema and delete all the contents of all the tables that OpenJPA knows about:

AIX HP-UX Linux Solaris

```
$ wsschema.bat -a refresh,deleteTableContents
```

Windows

```
$ wsschema.bat -a refresh,deleteTableContents
```

Drop the current database:

AIX HP-UX Linux Solaris

```
$ wsschema.sh -a dropDB
```

Windows

```
$ wsschema.bat -a dropDB
```

Write an XML representation of the current schema to the file *schema.xml*:

AIX HP-UX Linux Solaris

```
$ wsschema.sh -a reflect -f schema.xml
```

Windows

```
$ wsschema.bat -a reflect -f schema.xml
```

### Additional information

For more information read the JDBC information in the Apache OpenJPA documentation.

## wsdbgen command

The command supports utilization of the pureQuery feature in Java Persistence API (JPA) applications.

This command has been renamed wsdbgen for Feature Pack for OSGi Applications and JPA 2.0 and later releases. The command is used in the same way as the wsdb2gen command. The command, wsdb2gen, which implies for DB2 only, works only for DB2 database in WebSphere Application Server V7.0. In this release, the command can be used for DB2, Informix and Oracle databases. Because of that, a synonym, wsdbgen command, is introduced.

The JPA commands (.bat on Windows or .sh on UNIX) are run from the *profile_root*/bin directory, rather than from the *app_server_root*/bin directory to make sure that you have the latest version of the commands for your release.

## Syntax

The command syntax is as follows:

AIX HP-UX Linux Solaris

```
wsdbgen.sh [parameters]
```

Windows

```
wsdbgen.bat [parameters]
```

Before running the command, your persistence.xml file must be in the META-INF directory and the META-INF directory must be in the class path.

## Parameters

- **-help**: This parameter displays the help information.
- **-pu**: The name of the persistence unit defined in persistence.xml file.
- **-collection**: The collection-id which is assigned to package names. The default is NULLID.
- **-url**: The URL of the target database.

  This is used to validate the generated SQL. A URL must be specified either in the persistence.xml file or as a command option. If both are specified, the URL that is specified in the command option is used.
- **-user**: The user ID.
- **-pw**: The corresponding password to connect to target database.

  If this parameter is not specified, the value found in the persistence.xml file is used.
- **-package**: If this parameter is specified, the **-package** parameter takes the string value package name and a single database package with the specified name is generated. If the **-package** parameter is not specified, then one package is generated for each entity class. The entity name is used as package name if the **-package** option is not specified. The name length limit is the database limit -1, for example: 128 - 1 = 127.

## Usage

The persistence.xml file must be included in the application Java archive (JAR) file and is also used as input in the DB2 bind to create the DB2 package. The command requires a connection to a database to validate generated SQL. The database does not have to be the same as the run time database, but it should be at the same version and release level.

Ensure that the following JAR files are on the class path:

- pdq.jar
- pdqmgmt.jar
- db2jcc.jar
- db2jcc_licence_cu.jar

If the database URL specifies a DB2 for z/OS database, then the following JAR file must also be on the class path: db2jcc_licence_cisuz.jar

**Attention:** Read more about the DB2 JAR level compliance for IBM Optim PureQuery Runtime at the IBM Support website: System requirements for IBM Optim PureQuery Runtime for Linux, UNIX, and Windows.

**Attention:** You can review information about pureQuery StaticBinder in the Data Studio Information Center by reading the topic, "The pureQuery StaticBinder utility."

### Examples

#### DB2

AIX HP-UX Linux Solaris

```
wsdbgen.sh  -pu payroll -collection prod1 -url jdbc:db2://myhostname:50000/proddb  -user produser -pw secret
```

Windows

```
wsdbgen.bat  -pu payroll -collection prod1 -url jdbc:db2:\\myhostname:50000\proddb  -user produser -pw secret
```

#### Informix

AIX HP-UX Linux Solaris

```
wsdbgen.sh  -pu payroll -collection prod1 -url jdbc:ids://myhostname:9089/proddb  -user produser -pw secret
```

Windows

```
wsdbgen.bat  -pu payroll -collection prod1 -url jdbc:ids:\\myhostname:9089\proddb  -user produser -pw secret
```

## ANT task WsJpaDBGenTask

The ANT task WsJpaDBGenTask provides an alternative to the wsdbgen command.

The WsJpaDBGenTask ANT task utility supports utilizing the pureQuery feature in Java Persistence API (JPA) 2.0 and later applications that do not use DB2 databases. Instead of using the wsdbgen from the command line, you can use the example code in your ANT build XML file to use the WsJpaDBGenTask in your build process.

Both the PDQ runtime Java archive (JAR) files, `pdq.jar` and `pdqmgmt.jar`, must be specified using the ANT -lib option.

**Attention:** Read more about the DB2 JAR level compliance for pureQuery at the IBM Support website: System requirements for IBM Optim pureQuery Run time for Linux, UNIX, and Windows.

### Example

The following example is run in the Windows environment with the ANT command:

```
C:\jpa\ant jar -noclasspath -lib  c:/was8/dev/JavaEE/j2ee.jar
-lib ${app_server_root}/runtimes/com.ibm.ws.jpa.thinclient_8.0.0.jar
-lib c:/sqllib/java/db2jcc.jar
-lib c:/sqllib/java/db2jcc_license_cu.jar
-lib c:/sqllib/java/pdq.jar
-lib c:/sqllib/java/pdqmgmt.jar
```

When calling the ANT command, the JAR files for pureQuery, JPA, and the JDBC driver must be on the library list.

```
<?xml version="1.0"?>
<project name="sample" default="jar">
<taskdef name="enhancer" classname="org.apache.openjpa.ant.PCEnhancerTask" />
<taskdef name="wsdbgen" classname="com.ibm.websphere.persistence.pdq.ant.WsJpaDB2GenTask" />
<target name="clean" description="remove intermediate files">

</project>
```

# SQL statement batching for JPA applications

SQL statement batching can improve the performance of your application server.

## About this task

**Attention:** Support for SQL statement batching is no longer a WebSphere Application Server for JPA extension. You can find information regarding statement batching in the Apache OpenJPA documentation.

By default, statement batching is enabled for DB2 and Oracle databases. To enable SQL statement batching and to set the batch limit for JPA applications, you must configure the `persistence.xml` file. The following steps review how to enable and disable statement batching, and set the batch limit:

## Procedure

1. Define the UpdateManager property in the `persistence.xml` file. For example:

   ```
   <property name="openjpa.jdbc.UpdateManager"
   value="com.ibm.ws.persistence.jdbc.kernel.OperationOrderUpdateManager(batchLimit=100)"/>
   ```

   **Note:** The example shows that the SQL statement batch limit is set to `100`.

**Remember:** If you are using a DB2 or an Oracle database, by default the SQL statement batching is enabled and set to `batchLimit=100`. However, if you are using DB2 or Oracle, you are not required to specify this property in the `persistence.xml` file.

2. If you must disable SQL statement batching, set the batchLimit value to `0` or remove the property. However, if you are using a DB2 or an Oracle database, you must specify the DBDictionary property, database, and set the defaultBatchLimit to `0` . For example:

```
<property name="openjpa.jdbc.DBDictionary" value="db2(defaultBatchLimit=0)"/>
```

### Results

You have now updated the `persistence.xml` file to enable or disable statement batching and set the batch limit.

## Database generated version ID with JPA

Java Persistence API (JPA) for WebSphere Application Server has extended OpenJPA to work with database generated version IDs. These generated version fields, timestamp, or token, can be used to efficiently detect changes to a given row.

Trigger based version ID generation is supported for all databases that WebSphere Application Server supports. Support is based on two Version Strategies in JPA for WebSphere Application Server.

- @VersionStrategy("com.ibm.websphere.persistence.RowChangeTimestampStrategy"), if the entity version field type is Timestamp, and
- @VersionStrategy("com.ibm.websphere.persistence.RowChangeVersionStrategy"), if the entity version field type is Long

#### Database generated version ID example

In this example, the Entity class is defined with the new Version Strategy annotation. The Entity has a surrogate version column.

```
@Entity(name="Item")
@VersionColumn(name="versionField")
@VersionStrategy("com.ibm.websphere.persistence.RowChangeTimestampStrategy")
public class Item implements Serializable
{
 @Id
 private int id2;

 private String name;

 private double price;

   @OneToOne
   private Owner master;
}
```

The create table statement is as follows:

```
CREATE TABLE ITEM
(ID2  INT  NOT NULL,
 NAME  VARCHAR(50) ,
 PRICE   DOUBLE,
 OWNER_ID INT,
             VERSIONFIELD GENERATED ALWAYS FOR EACH ROW ON
              UPDATE AS ROW CHANGE TIMESTAMP
         PRIMARYKEY(ID2));
```

During any updates to Item, insert or update, the VersionColumn value is updated in the database. After the update, the value for VersionColumn is retrieved from the database and updated in the in-memory

object. Thereby the objects in the data cache reflect the correct version value. Here the Entity is using the @VersionColumn, which produces a Surrogate Version ID rather than defining an explicit field in the entity.

The Entity could also use @Version annotation to define an explicit version field. The explicit version field could be of type Long or Timestamp corresponding to the @VersionStrategy. During any updates to Item, insert or update, the Version value is updated in the database. After the update, the value for Version is retrieved from the database and updated in the in memory object. Thereby the objects in the data cache reflect the right version value.

This is an example where the Entity has a version field defined, and the type Timestamp matches the RowChangeTimestampStrategy in the @VersionStrategy. If the version field type is using type long, then the RowChangeVersionStrategy should be annotated to match:

```
@Entity(name="Item")
@VersionStrategy("com.ibm.websphere.persistence.RowChangeTimestampStrategy")
public class Item implements Serializable

{
 @Id
 private int id2;

 private String name;

 private double price;

   @Version
   private Timestamp versionField;

   @OneToOne
   private Owner master;
}
```

**Note:** Be aware of the following conditions when you use RowChangeVersionStrategy:

- For z/OS DB2 V9 and Linux, UNIX, and Windows DB2 V9.5, the generated database column must be of type timestamp, but both the RowChangeTimestampStrategy and the RowChangeVersionStrategy are supported. Microsoft SQL Server only supports a non-timestamp generated version ID that goes with the RowChangeVersionStrategy . To use the RowChangeTimestampStrategy, you must use a trigger on a timestamp field in the database. For other databases, you can use triggers to simulate database version generation and use either strategy.
- For z/OS DB2 V9, install the PTF for APAR PK67706, and ensure that you have installed the required level of IBM Optim PureQuery Runtime (1.3.100 or later) and JCC drivers (3.52.95 or later).

# Mapping persistent properties to XML columns for JPA

If your database supports Extensible Markup Language (XML) column types, you can use mapping tools to manage XML objects. You have the choice of mapping XML columns to a Java string or a Java byte array field.

## About this task

**Attention:** Support for mapping persistent properties to XML columns is no longer a WebSphere Application Server for JPA extension. You can find information regarding XML mapping in the Apache OpenJPA documentation.

JPA for the application server supports the management of XML objects by using a third-party solution for mapping management. These mapping techniques make using the XML objects as strings or byte arrays difficult.

DB2, Oracle, and SQLServer databases support XML column types, XPath queries, and indices over these columns.

**Persistent properties to XML mapping**

An embedded class with XML column support must use XML marshaling to write the data to the XML column and unmarshalling to retrieve the data from the XML column. The path expressions and predicates over the embedded class are converted to XML predicates, XPATH expressions, or XQuery expressions and are written to the database.

WebSphere Application Server supports JPA applications to use a third-party tool for XML mapping. This is done through the extension points for custom field mappings. The third-party mapping tool uses the extension points by providing a custom value handler for the persistent fields that are mapped to the XML columns. In OpenJPA, this value handler is named org.apache.openjpa.xmlmapping.XmlValueHandler and this handler requires the @Strategy annotation on the Java field that is mapped to the XML column.

## Procedure

1. Annotate the entity property using the XML value handler strategy. The mapping of persistent properties to XML columns requires the @Strategy and the @Persistent annotation.

   ```
   @Persistent
   @Strategy("org.apache.openjpa.xmlmapping.XmlValueHandler")
   ```

   The XML value handler for the persistent property is set to org.apache.openjpa.xmlmapping.XmlValueHandler.
2. Change the default for fetch type if it is necessary. For example:

   ```
   @Persistence(fetch=FetchType.LAZY)
   ```

   The fetch type is now LAZY. If a value for the fetch type is not entered, the default is set to EAGER.
3. Annotate your embedded classes with the binding annotations for Java API for XML Binding (JAXB). These bindings can be created from an XML schema by using the Java Architecture for XML Binding Compiler (XJC).
4. Make sure that the class that maps to the root of the XML document is annotated with @XmlRootElement, in addition to the other annotations.
5. Compile your Java sources.
6. Run the enhancer tool on the entities. Refer to the topic on the entity enhancer tool for more information.

## Example

For example, shipAddress, a property of Order Entity, is mapped to XML column shipaddr:

```
@Entity
public class Order {
 @Id
 @GeneratedValue(strategy=GenerationType.IDENTITY)
  int oid;
 @Persistent
 @Strategy("org.apache.openjpa.xmlmapping.XmlValueHandler")
      @Column(name="shipaddr")
      Address shipAddress;
...
```

The OpenJPA mapping tool generates a SHIPADDR column with XML type in the table definition for ORDER table.

# Directory conventions

References in product information to *app_server_root*, *profile_root*, and other directories imply specific default directory locations. This topic describes the conventions in use for WebSphere Application Server.

## Default product locations (distributed)

The following file paths are default locations. You can install the product and other components or create profiles in any directory where you have write access. Multiple installations of WebSphere Application Server - Express products or components require multiple locations. Default values for installation actions by root and nonroot users are given. If no nonroot values are specified, then the default directory values are applicable to both root and nonroot users.

*app_client_root*

*Table 109. Default installation root directories for the Application Client for IBM WebSphere Application Server.*

*This table shows the default installation root directories for the Application Client for IBM WebSphere Application Server.*

| User | Directory |
|---|---|
| Root | AIX `/usr/IBM/WebSphere/AppClient` (Java EE Application client only)<br>HP-UX Linux Solaris `/opt/IBM/WebSphere/AppClient` (Java EE Application client only)<br>Windows `C:\Program Files\IBM\WebSphere\AppClient` |
| Nonroot | AIX HP-UX Linux Solaris *user_home*`/IBM/WebSphere/AppClient` (Java EE Application client only)<br>Windows `C:\IBM\WebSphere\AppClient` |

*app_server_root*

*Table 110. Default installation directories for WebSphere Application Server.*

*This table shows the default installation directories for WebSphere Application Server - Express.*

| User | Directory |
|---|---|
| Root | AIX `/usr/IBM/WebSphere/AppServer`<br>HP-UX Linux Solaris `/opt/IBM/WebSphere/AppServer`<br>Windows `C:\Program Files\IBM\WebSphere\AppServer` |
| Nonroot | AIX HP-UX Linux Solaris *user_home*`/IBM/WebSphere/AppServer`<br>Windows *user_home*`\IBM\WebSphere\AppServer` |

*component_root*

The component installation root directory is any installation root directory described in this topic. Some programs are for use across multiple components—in particular, the Web Server Plug-ins, the Application Client, and the IBM HTTP Server. All of these components are part of the product package.

*gskit_root*

IBM Global Security Kit (GSKit) can now be installed by any user. GSKit is installed locally inside the installing product's directory structure and is no longer installed in a global location on the target system. The following list shows the default installation root directory for Version 8 of the GSKit, where *product_root* is the root directory of the product that is installing GSKit, for example IBM HTTP Server or the web server plug-in.

AIX HP-UX Linux Solaris

*product_root*/gsk8

Windows

*product_root*\gsk8

### *profile_root*

*Table 111. Default profile directories.*

*This table shows the default directories for a profile named profile_name on each distributed operating system.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/AppServer/profiles/*profile_name*<br>HP-UX Linux Solaris /opt/IBM/WebSphere/AppServer/profiles/*profile_name*<br>Windows C:\Program Files\IBM\WebSphere\AppServer\profiles*profile_name* |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/AppServer/profiles<br>Windows *user_home*\IBM\WebSphere\AppServer\profiles |

### *plugins_root*

*Table 112. Default installation root directories for the Web Server Plug-ins.*

*This table shows the default installation root directories for the Web Server Plug-ins for WebSphere Application Server.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/Plugins<br>HP-UX Linux Solaris /opt/IBM/WebSphere/Plugins<br>Windows C:\Program Files\IBM\WebSphere\Plugins |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/Plugins<br>Windows C:\IBM\WebSphere\Plugins |

### *wct_root*

*Table 113. Default installation root directories for the WebSphere Customization Toolbox.*

*This table shows the default installation root directories for the WebSphere Customization Toolbox.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/Toolbox<br>HP-UX Linux Solaris /opt/IBM/WebSphere/Toolbox<br>Windows C:\Program Files\IBM\WebSphere\Toolbox |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/Toolbox<br>Windows C:\IBM\WebSphere\Toolbox |

### *web_server_root*

*Table 114. Default installation root directories for the IBM HTTP Server.*

*This table shows the default installation root directories for the IBM HTTP Server.*

| User | Directory |
|---|---|
| Root | AIX `/usr/IBM/HTTPServer`<br>HP-UX Linux Solaris `/opt/IBM/HTTPServer`<br>Windows `C:\Program Files\IBM\HTTPServer` |
| Nonroot | AIX HP-UX Linux Solaris *user_home*`/IBM/HTTPServer`<br>Windows `C:\IBM\HTTPServer` |

# Assembling applications that use the Java Persistence API

## Assembling a JPA application in a Java EE environment

You have developed and configured your applications to work with the Java Persistence API (JPA). Now you need to package the JPA applications for your environment.

### About this task

### Procedure

Package the application. There are several packaging options for an application that uses JPA in a Java EE environment. Choose the packaging option that best suits the JPA usage and configuration within the modules of your application. These are some of the most common packaging options. For a definitive list of packaging options, see the Java Persistence API specification.

**Note:** IBM Optim PureQuery Runtime, add the *persistence_unit_name*`.pdqxml` file to the JPA application JAR file. The files are located in same `META-INF` directory where the `persistence.xml` file is located. These persistence files were created during the development task. See the topic, Developing JPA applications for a Java EE environment for more information.

- For a standalone Enterprise JavaBeans (EJB) module or a stand-alone application client module, package the EJB and application client modules in a standard Java archive (JAR) file. Ensure that you package the application with these conditions:
  - The JAR file must contain your EJB class files or the Java class files for the application client.
  - The META-INF directory of the archive must include your `persistence.xml` file.
  - If your application uses mapping files, `orm.xml`, or a custom mapping file, the JAR file must also contain those files. If the location of the `orm.xml` file is not specified in the persistence unit, the default location is the META-INF directory of the JAR file.
  - The Criteria Metamodel class files that are generated by the Annotation Processor when you developed your application needs to be included in the JAR file in the same location as the entity class files.
- For a stand-alone web module, package the application in a standard web application archive (WAR) file. Ensure that you package the application with these conditions:
  - The Criteria Metamodel class files that are generated by the Annotation Processor while developing your application needs to be included in the WAR file in the same location as the entity class files.
  - The WAR file must contain your web application class files. The web application class files must be included in the `WEB-INF/classes` directory or in a JAR file that is located in the `WEB-INF/lib` directory of the WAR file.

  - The `persistence.xml` file must be included in the `WEB-INF/classes/META-INF` directory or in the META-INF directory of a JAR file that is included in your `WEB-INF/lib` directory of your WAR file.
  - If your application uses mapping files, `orm.xml`, or a custom mapping file, the WAR file must also contain those files. Mapping files can reside in the `WEB-INF/classes` directory or in a JAR file that is contained within the `WEB-INF/lib` directory of the WAR file. Use the <mapping-file> element of the `persistence.xml` file to specify the location of mapping files. For example:

    ```
    <mapping-file>META-INF/JPAorm.xml</mapping-file>
    ```

- For enterprise application that contains one or more modules, package the application in a standard Enterprise application archive (EAR) file. An enterprise application can contain one ore more EJB module, web module, or application client module. Ensure that you package the application with these conditions:
  - If multiple modules use the same persistence unit, you can create a persistence archive and package the persistence archive within the EAR file.
  - Include your entity classes, associated Criteria Metamodel classes, any necessary supporting classes, the `persistence.xml` file, and additional mapping files in the persistence archive file. Follow the packaging rules for EJB and application client modules for the location of your `persistence.xml` file and mapping files.
  - Each module that uses the persistence archive must have a class path entry in its `META-INF/MANIFEST.MF` file. Here is an example manifest file:

    ```
    Manifest-Version: 1.0
    Class-Path: MyJPAEntities.jar
    ```

  - If your modules use separate persistence units and share entity classes, you can package the entity classes in a persistence archive and specify different `persistence.xml` file and mapping files for each module. If the modules do not share entity classes or a persistence configuration, package each module as a standalone EJB module, a stand-alone application client module, or a standalone web application archive and then package them in the EAR file.

### What to do next

For more information about the commands, classes or other OpenJPA information, refer to the Apache OpenJPA User Guide.

## Assembling JPA applications for a Java SE environment

You have developed and configured your applications to work with the Java Persistence API (JPA). Now you must package the JPA applications for your environment.

### About this task

For this task, you must specify the `com.ibm.ws.jpa.thinclient_8.0.0.jar` stand-alone Java archive (JAR) file in your class path. This stand-alone JAR file is available from the client and server installation images. The location of this file on the client installation image is ${*app_client_root*}/runtimes/com.ibm.ws.jpa.thinclient_8.0.0.jar. The location of this file on the server installation image is ${*app_server_root*}/runtimes/com.ibm.ws.jpa.thinclient_8.0.0.jar.

### Procedure

1. Package the application.

   **Note:** Package the persistence units in separate JAR files to make them more accessible and reusable. If you package the persistence units this way, they can be tested outside the container both with and without the occurrence of database persistence. The persistence units can be included in stand-alone applications or they can be packaged into EAR files as persistence archive files. If you package the persistence unit into a persistence archive file, all

of the application components must be able to access the persistence archive. The application that uses the persistence units must declare a dependency on the persistence archive using the `MANIFEST.MF Class-Path:` declaration.

The Criteria Metamodel class files that are generated by the Annotation Processor when you developed your JPA application, must be included in the JAR file in the same location as the entity class files.

**Note:** If you are using IBM Optim PureQuery Run time, add the *persistence_unit_name*`.pdqxml` files to the JPA application JAR file. The files are located in same `META-INF` directory where your `persistence.xml` file is located. These persistence files were created during the development task, Developing JPA applications for a Java SE environment.

To package the application use the following command:

```
jar -cvf ${jar_Name} ${entity_Path}
```

where ${*jar_Name*} represents the name of the JAR file to create, and ${*entityPath*} represents the root location where the entities reside, which is where you compiled them. Make sure that your ${`entity_Path`} also contains the `META-INF/persistence.xml` file.

2. When you run your stand-alone application, specify the JAR files in your class path when starting your application. The JPA runtime starts the stand-alone JAR file, `com.ibm.ws.jpa.thinclient_8.0.0.jar`. For example, use the following Java call to run the com.xyz.Main stand-alone application:

```
java -cp /your/directory/${jar_Name}
-javaagent:${app_client_root}/runtimes/com.ibm.ws.jpa.thinclient_8.0.0.jarcom.xyz.Main
```

### What to do next

For more information about any of the commands, classes or other OpenJPA information, refer to the Apache OpenJPA User Guide.

## Using JPA access intent

Java Persistence API (JPA) access intent specifies the isolation level and lock level used when reading data from a data source. Access intent controls the Java Database Connectivity (JDBC) isolation level and whether read, update, or exclusive locks are acquired when retrieving data.

### About this task

For a JPA persistence provider on the application server, the application can specify isolation and ReadLockMode based on a TaskName. The TaskName provides a better control over applying these characteristics. The application defines a set of entity types and corresponding access intent for each TaskName defined in a persistence unit.

**Restriction:**

- Access intent is available for application in the Java EE server environment
- Access intent is applicable to non-query entity manager interface methods. Query uses query hint interface to set its isolation and read lock values.
- Access intent is only available for DB2 databases.
- Access intent is in effect only when pessimistic lock manager is used. Add the following to the persistence unit property list. <property name="openjpa.LockManager" value="pessimistic"/>

*Table 115. Access intent Properties and Descriptions. The following table compares the Enterprise JavaBeans (EJB) 2.x entity bean access intent with the JPA access intent properties:*

| WebSphere EJB 2.x entity bean access intent | JPA access intent | Description |
|---|---|---|
| optimistic | isolation: Read Committed | Data is read but no lock is held. Version ID is used on update to ensure data integrity. Other transactions can read and update data. |
| | lockManager: Optimistic | |
| | query Hint: ReadLockMode: READ | |
| pessimistic read | isolation: Repeatable Read | Data is read with shared locks. Other transactions attempting to update data are blocked. |
| | lockManager: Optimistic | |
| | query Hint: ReadLockMode: READ | |
| pessimistic update | isolation: Repeatable Read | Data is retrieved with update or exclusive lock. Other writes are blocked until commit. This access intent can be used to serialize update access to data when there are multiple writers. |
| | lockManager: Pessimistic | |
| | query Hint: ReadLockMode: WRITE | |
| pessimistic exclusive | isolation: Serializable | Data is retrieved with update or exclusive lock. Other writes are blocked until commit. This access intent can be used to serialize update access to data when there are multiple writers. |
| | lockManager: Pessimistic | |
| | query Hint: ReadLockMode:WRITE | |

A TaskName is set on a transaction context by one of the following:

- TaskName is automatically set in the EJB container when a transaction begins using WebSphere local transaction (EJB unspecified transaction), JTA global transaction in a Container-Managed Transaction (CMT) or user-initiated global transaction in a Bean-Managed Transaction (BMT).
- TaskName is manually set in an application using the TaskNameAccessor API provided for JPA.

Using task names supports the specification of access intent on a request scope rather than specifying it in the `persistence.xml` file, which has an application scope across all entities. Often a query is contained in a method or component which is used in many different transaction contexts. Some of these contexts might require repeatable-read and update lock intent but other contexts do not.

Isolation level and read locks can be specified on:

- An application scope in the `persistence.xml` file. These isolation levels and read lock types are properties specified in the `persistence.xml` file. They apply to all entities that are defined in the persistence unit.
- A transaction scope in the task name. Transaction scoped hints override application scope values.
- Query instance with a query hint. Query hint can be used to override isolation and ReadLockMode for a particular query instance. A query hint overrides isolation level and read locks specified at the application or transaction scope.

## Procedure

1. “Setting a TaskName using TaskNameAccessor API” on page 803 This task explains how to use the TaskNameAccessor API to set JPA TaskName at run time.
2. “Specifying TaskName in a JPA persistence unit” on page 804 This task explains how to specify a TaskName in JPA persistence unit .

## What to do next

For more information about Access intent, see the topic, Access intent service.

## Setting a TaskName using TaskNameAccessor API

Using the TaskNameAccessor API to set Java Persistence API (JPA) TaskName at runtime.

### About this task

In the Enterprise JavaBeans (EJB) container, a task name is automatically set by default upon a transaction begins. This action is performed when a component or business method is invoked in a CMT session bean or when an application invoke the `sessionContext.getTransaction().begin()` in a BMT session bean. This TaskName consists of a concatenation of the fully package qualified session bean type, a dot character and the method name. For example: `com.acme.MyCmtSessionBean.methodABC`.

If using JPA in the context of the web container, an application must use the TaskNameAccessor API to set the TaskName in the current thread of execution.

**Note:** Once a TaskName is set on a transaction context, application must not set the TaskName again in the same transaction. This will avoid problems with on the JDBC connection for different database access.

This example contains the TaskNameAccessor API definition

```
package com.ibm.websphere.persistence;

public abstract class TaskNameAccessor {

 /**
  * Returns the current task name attached in the current thread context.
  * @return current task name or null if none is found.
  */
 public static String getTaskName ();

 /**
  * Add a user-defined JPA access intent task name to the current thread
  * context.
  *
  * @param taskName
  * @return false if an existing task has already attached in the current
  *         thread or Transaction Synchronization Registry (TSR) is not
  *         available (i.e. in JSE environment).
  */
 public static boolean setTaskName(String taskName);

}
```

This code example shows how to set a TaskName using TaskNameAccessor.

```
package my.company;

@Remote
class Ejb1 {
    // assumer no tx from the caller
    @TransactionAttribute(Requires)
    public void caller_Method1() {

        // an implicit new transaction begins
        // TaskName "my.company.Ejb1.caller_Method1" set on TSR

        ejb1.callee_Method?();
    }

    @TransactionAttribute(RequiredNew)
    public void callee_Method2() {

        // an implicit new transaction begins i.e. TxRequiredNew.
        // TaskName "my.company.Ejb1.callee_Method2" set on TSR
```

```
    }

    @TransactionAttribute(Requires)
    public void callee_Method3() {

        // In caller's transaction, hence TaskName remains
        //     "my.company.Ejb1.caller_Method1"
    }

    @TransactionAttribute(NotSupported)
    public void callee_LocalTx () {

        // Unspecified transaction, a new local transaction implicitly started.
        // TaskName "my.company.Ejb1.callee_LocalTx" set on TSR
    }

}
```

**Attention:** In the above example, an application must be aware of transaction boundary will be subtly changed if Ejb1 uses local interface (@Local). For example, when `caller_Method1()` calls `callee_Method3` or `callee_LocalTx`, this will be treated as a Java method call. No EJB transaction semantics are honored.

### What to do next

Once you have completed this step, continue on with the topic Specify TaskName in a JPA persistence unit.

## Specifying TaskName in a JPA persistence unit

Specifying a TaskName in Java Persistence API (JPA) persistence unit

### About this task

A TaskName is defined in the `persistence.xml` file using the `wsjpa.AccessIntent` property name in a persistence unit. The property value is a list of TaskNames, entity types and access intent definitions. The following example shows the contents of the `wsjpa.AccessIntent` property name in a persistence unit.

```
<property name  = "wsjpa.AccessIntent"
         value = "Tasks=' <taskName> { <entityName> ( <isolationLockValue> ) } ' "/>
                         A            A              A                     | | |
                         |            |              +--------- , --------+ | |
                         |            |                                     | |
                         |            +------------------ , -----------------+ |
                         +----------------------- , --------------------------+
  Tasks                        ::= <task> [ ',' <task> ]*

  <task>                       ::= <taskName> '{' <entity> [ ',' <entity> ]* '}'

  <entity>                     ::= <entityName> '(' <isolationLockValues> ')'

  <taskName>                   ::= <fully_qualified_identifier>

  <entityName>                 ::= <fully_qualified_identifier>

  <fully_qualified_identifier> ::= <identifier> [ '.' <identifier> ]*

  <identifier>                 ::= <idStartCharacter> [ <idCharacter> ]*

  <idStartCharacter>           ::= Character.isJavaIdentifierStart | '?' | '*'

  <idStartCharacter>           ::= Character.isJavaIdentifierPart  | '?' | '*'

  <isolationLockValues>        ::= <isolationLockValue> [ ',' <isolationLockValue> ]

  <isolationLockValue>         ::= <isolation> | <readLock>
```

```
<isolation>                 ::= "isolation" '=' <isolationValue>

<readLock>                  ::= "readlock" '=' <readlockValue>

<isolationValue>            ::= "read-uncommitted"|"read-committed"|"repeatable-read"|"serializable"

<readlockValue>             ::= "read" | "write"
```

Before setting the TaskName in a persistence unit, keep the following in mind:

- White spaces are ignored between tokens.
- Only <isolation> and <readLock> contents are not case sensitive.
- <TaskName> is in the form of a fully package qualified method name, such as com.acme.bean.MyBean.increment, or an arbitrary user-defined task name, such as MyProfile.
- <entityName> is in the form of a fully package qualified class name such as com.acme.bean.Entity1.
- The wild card characters '?' or '*' can be used in <TaskName> and <entityName>. "?" matches any single character and "*" matches zero or more sequence characters.
- Only hintNames isolation and readLock are allowed on a task definition and the order is not significant
- If readLock has the value `write`, then isolation must be `repeatable-read` or `serializable`
- If readLock has the value `read`, it has no effect if the isolation is `read-uncommitted`.

The following code example shows how to specify a TaskName in JPA persistence unit.

```
package my.company;

@Remote
class Ejb1 {
    // assumer no tx from the caller
    @TransactionAttribute(Requires)
    public void caller_Method1() {

        // an implicit new transaction begins
        // TaskName "my.company.Ejb1.caller_Method1" set on TSR

        ejb1.callee_Method?();
    }

    @TransactionAttribute(RequiredNew)
    public void callee_Method2() {

        // an implicit new transaction begins i.e. TxRequiredNew.
        // TaskName "my.company.Ejb1.callee_Method2" set on TSR
    }

    @TransactionAttribute(Requires)
    public void callee_Method3() {

        // In caller's transaction, hence TaskName remains
        //     "my.company.Ejb1.caller_Method1"
    }

    @TransactionAttribute(NotSupported)
    public void callee_LocalTx () {

        // Unspecified transaction, a new local transaction implicitly started.
        // TaskName "my.company.Ejb1.callee_LocalTx" set on TSR
    }

}
```

Since a wild card can be used to specify TaskName and entity type, multiple specification matches may occur at runtime. The order defined in the `wsjpa.AccessIntent` property will be used to search for task names and entity types.

```
<properties>
  <property name="wsjpa.AccessIntent" value="Tasks="
        *.Task1 { *.Employee1 ( isolation=read-uncommitted                ),
                  *.Employee? ( isolation=repeatable-read,  readlock=write ),
                },
        *       { *.Employee3 ( isolation=serializable,     readlock=write ) },
      '" />
</properties>
```

# Associating persistence providers and data sources

Java Persistence API (JPA) applications specify the underlying data source that is used by the persistence provider to access the database.

## About this task

The application server provides three methods for defining the data sources in the `persistence.xml` file.

## Procedure

- Explicitly specify the Java Naming and Directory Interface (JNDI) name in the `persistence.xml` file, and the application directly references the data source. Switching to another data source requires an update to the `persistence.xml` file.

  JPA has two transactional patterns for accessing a data source:

  – The Java Transaction API (JTA) resource pattern depends on global transactions. The JTA resource pattern is typically used within the scope of an Enterprise JavaBeans (EJB) session facade. This supports the session bean to control transaction and security contexts while JPA handles the persistence mappings. In this case, the application does not use the EntityTransaction interface but relies on the EntityManager enlisted with the global transaction when it is accessed.

  – The non-JTA resource pattern is used when dealing with a single resource in the absence of global transactions. The non-JTA resource pattern is typically used within the scope of a web application or an application client. The application controls the transaction with the data source with the EntityTransaction interface.

    Within the application server, the use of the <non-jta-data-source> element requires a special configuration for a non-transactional data source. Data sources that are configured for the application server do not function as a <non-jta-data-source>, because all data sources that are configured by the application server are automatically enlisted with the current transactional context. To prevent this automatic enlistment, add an additional data source custom property `nonTransactionalDataSource=true`:

    1. Select **Resources** > **JDBC** > **Data sources**
    2. Select the name of the data source that you want to configure.
    3. Select **WebSphere Application Server data source properties** from the **Additional Properties** heading.
    4. Select **Non-transactional data source**.
    5. Click **OK**.

**Note:** The JPA specification assumes that connections are obtained with an isolation level that does not hold long-term locks in the database, such as `READ_COMMITTED`. This might not match the WebSphere Application Server default isolation level, which is `REPEATABLE_READ` for most databases. You can find the level that is used for your database by reading the topic, Requirements for setting isolation level.

If the default for your database is not READ_COMMITTED, you can change the default by adding an additional data source custom property webSphereDefaultIsolationLevel.

*Table 116. Isolation level values. This table shows valid isolation level values.*

| Value | Isolation Level |
|---|---|
| 1 | READ_UNCOMMITTED |
| 2 | READ_COMMITTED (JPA default) |
| 4 | REPEATABLE_READ (WebSphere Application Server default) |
| 8 | SERIALIZABLE |

If the isolation level is set to a value that holds long-term read locks, configure the JPA provider to use Pessimistic Locking instead of the default Optimistic Locking. For the JPA provider included with WebSphere Application Server, you can do this by adding the following properties to persistence.xml file:

```
<property name="openjpa.Optimistic"="false"/>
<property name="openjpa.LockManager"=pessimistic"/>
```

The JPA specification mandates that the data sources that are defined in <jta-data-source> and <non-jta-data-source> elements of a persistence unit register in the JNDI name space. For example, the persistence.xml file should contain an entry like the following:

```
<jta-data-source>jdbc/DataSourceJNDI</jta-data-source>
```

- The JPA for WebSphere Application Server solution extends the JNDI data-source implementation to allow you to reference data sources in the component name space. In the EJB or web module deployment descriptor file, this is the <resource-ref> element. You can prefix the data source with java:comp/env/ so the application indirectly references the data source by using the local JNDI name. In this association, the application does not require updates, you change <resource-ref> to use another data source. See the following example:

  ```
  <jta-data-source>java:comp/env/jdbc/DataSourceJNDI</jta-data-source>
  ```

  **Note:** The JPA specification does not require implementations to include data sources referenced in local JNDI names, so this method of reference might not be portable to other implementations of JPA.

- You can declare openjpa.Connection* properties in the persistence unit as follows:

  ```
  <property name="openjpa.ConnectionDriverName" value="org.apache.derby.jdbc.EmbeddedDriver" />
  <property name="openjpa.ConnectionURL" value="jdbc:derby:target/database/jpa-test-database;create=true"/>
  ```

  OR

  You can use alternative standard JPA properties that are equivalent to the OpenJPA properties, such as:

*Table 117. Standard JPA 2.0 property equivalents. Standard JPA 2.0 properties and the OpenJPA equivalents.*

| Standard JPA 2.0 | OpenJPA Equivalent |
|---|---|
| javax.persistence.jdbc.driver | openjpa.ConnectionDriverName |
| javax.persistence.jdbc.url | openjpa.ConnectionURL |

## What to do next

For information about configuring data sources, see the topic on creating and configuring a data source.

For information about data sources and JPA, see the section on persistence in the Apache OpenJPA User Guide.

# Chapter 13. Developing Internationalization service

This page provides a starting point for finding information about globalization and the internationalization service, a WebSphere extension for improving developer productivity.

With the internationalization service, you can automatically recognize the time zone and location information of the calling client so that your application can act appropriately. The technology enables you to deliver each user, around the world, the right date and time information, the appropriate currencies and languages, and the correct date and decimal formats.

This documentation also includes information about internationalizing interface strings using the localizable-text application programming interface.

## Task overview: Globalizing applications

An application that can present information to users according to regional cultural conventions is said to be *globalized*: The application can be configured to interact with users from different localities in culturally appropriate ways. In a globalized application, a user in one region sees error messages, output, and interface elements in the requested language. Date and time formats, as well as currencies, are presented appropriately for users in the specified region. A user in another region sees output in the conventional language or format for that region. Globalization consists of two phases: *internationalization* (enabling an application component for multicultural support) and *localization* (translating and implementing a specific regional convention). This product supports globalization through the use of its localizable-text API and internationalization service.

### Procedure

- Make sure the server runtime environment is properly configured.

  For more information about supported locales and character encodings, see “Working with locales and character encodings” on page 811.
- Implement message catalogs in your application by using the localizable-text API.

  This product supports the maintenance and deployment of centralized message catalogs for the output of properly formatted, language-specific (*localized*) interface strings.

  For more information about the localizable-text API, see “Task overview: Internationalizing interface strings (localizable-text API)” on page 814.
- Implement more extensive locale support by using the internationalization service.

  With the internationalization service, you can manage the distribution of the internationalization information, or *internationalization context*, that is necessary to support globalized Java Platform, Enterprise Edition (Java EE) application components. Supported application components also include web service client environments and web service-enabled enterprise beans.

  For more information about the internationalization service, see “Task overview: Internationalizing application components (internationalization service)” on page 825.

## Globalization

An application that can present information to users according to regional cultural conventions is said to be *globalized*: The application can be configured to interact with users from different localities in culturally appropriate ways. In a globalized application, a user in one region sees error messages, output, and interface elements in the requested language. Date and time formats, as well as currencies, are presented appropriately for users in the specified region. A user in another region sees output in the conventional language or format for that region. Globalization consists of two phases: *internationalization* (enabling an application component for multicultural support) and *localization* (translating and implementing a specific regional convention).

© IBM Corporation 2009

Historically, the creation of globalized applications has been restricted to large corporations writing complex systems. However, given the rise in distributed computing and in the use of the World Wide Web, application developers are pressured to globalize a much wider variety of applications. This trend requires making globalization techniques much more accessible to application developers.

Internationalization of an application is driven by two variables, the time zone and the locale. The *time zone* indicates how to compute the local time as an offset from a standard time like Greenwich Mean Time. The *locale* is a collection of information about language, currency, and the conventions for presenting information like dates. A time zone can cover many locales, and a single locale can span time zones. With both time zone and locale, the date, time, currency, and language for users in a specific region can be determined.

By convention, a given locale is specified with a pair of codes (for language and region) that are governed by different standards. The ISO-639 standard governs the language code; the ISO-3166 standard governs the regional code. In notation, the two codes are typically joined by an underscore (_) character, for example, en_US for English in the United States. In Java code, locales are set and retrieved by means of the java.util.Locale class.

## A first step: Localization of interface strings

In an application that is not globalized, the user interface is unalterably written into the application code. Internationalizing a user interface adds a layer of abstraction into the design of an application. The additional layer of abstraction enables you to localize the application for each locale that must be supported by the application.

In a localized application, the locale determines the message catalog from which the application retrieves message strings. Instead of printing an error message, the application represents the error message with some language-neutral information; in the simplest case, each error condition corresponds to a key. To print a usable error message, the application looks up the key in a *message catalog*. Each message catalog is a list of keys with associated strings. Different message catalogs provide strings for the different languages that are supported. The application looks up the key in the appropriate catalog, retrieves the corresponding error message in the requested language, and prints the string for the user.

Localization of text can be used for far more than translating error messages. For example, by using keys to represent each element in a graphical user interface (GUI) and by providing the appropriate message catalogs, the GUI (buttons, menus, and so on) can support multiple languages. Extending support to additional languages requires that you provide message catalogs for those languages; in many cases, the application needs no further modification.

The localizable-text package is a set of Java classes and interfaces that can be used to localize the strings in distributed applications easily. Language-specific string catalogs can be stored centrally so that they can be maintained efficiently.

## Globalization challenges in distributed applications

With the advent of Internet-based business computational models, applications increasingly consist of clients and servers that operate in different geographical regions. These differences introduce the following challenges to the task of designing a solid client-server infrastructure:

**Clients and servers can run on computers that have different endian architectures or code sets**

Clients and servers can reside in computers that have different endian architectures: A client can reside in a little-endian CPU, while the server code runs in a big-endian one. A client might want to call a business method on a server running in a code set different from that of the client.

A client-server infrastructure must define precise endian and code-set tracking and conversion rules. The Java platform has nearly eliminated these problems in a unique way by relying on its

Java virtual machine (JVM), which encodes all of the string data in UCS-2 format and externalizes everything in big-endian format. The JVM uses a set of platform-specific programs for interfacing with the native platform. These programs perform any necessary code set conversions between UCS-2 and the native code set of a platform.

**Clients and servers can run on computers with different locale settings**

Client and server processes can use different locale settings. For example, a Spanish client might call a business method upon an object that resides on an American English server. Some business methods are locale-sensitive in nature; for example, given a business method that returns a sorted list of strings, the Spanish client expects that list to be sorted according to the Spanish collating sequence, not in the English collating sequence of the server. Because data retrieval and sorting procedures run on the server, the locale of the client must be available to perform a legitimate sort.

A similar consideration applies in instances where the server has to return strings containing date, time, currency, exception messages, and so on, that are formatted according to the cultural expectations of the client.

**Clients and servers can reside in different time zones**

Client and server processes can run in different time zones. To date, all internationalization literature and resources concentrate mainly on code set and locale-related issues. They have generally ignored the time zone issue, even though business methods can be sensitive to time zone as well as to locale.

For example, suppose that a vendor makes the claim that orders received before 2:00 PM are processed by 5:00 PM the same day. The times given, of course, are in the time zone of the server that is processing the order. It is important to know the time zone of the client to give customers in other time zones the correct times for same-day processing.

Other time zone-sensitive operations include time stamping messages logged to a server, and accessing file or database resources. The concept of Daylight Savings Time further complicates the time zone issue.

Java Platform, Enterprise Edition (Java EE) provides support for application components that run on computers with differing endian architecture and code sets. It does not provide dedicated support for application components that run on computers with different locales or time zones.

The conventional method for solving locale and time zone mismatches across remote application components is to pass one or more extra parameters on all business methods needed to convey the client-side locale or time zone to the server. Although simple, this technique has the following limitations when used in Enterprise JavaBeans (EJB) applications:

- It is intrusive because it requires that one or more parameters be added to all bean methods in the call chain to locale-sensitive or time zone-sensitive methods.
- It is inherently error-prone.
- It is impracticable within applications that do not support modification, such as legacy applications.

The internationalization service addresses the challenges posed by locale and time zone mismatch without incurring the limitations of conventional techniques. The service systematically manages the distribution of internationalization contexts across the various components of EJB applications, including client applications, enterprise beans, and servlets. For more information, see “Task overview: Internationalizing application components (internationalization service)” on page 825.

## Working with locales and character encodings

Internationalization support for this product relies on that provided by the Java Platform, Standard Edition (JSE). Support varies by platform.

### Procedure

- Verify that the operating system on which the application server is installed supports the locales and encodings that you plan to use.

  Java internationalization support might use underlying services of the operating system. For example, if user IDs for your server are expected to contain non-English characters, make sure that the operating system is configured to process those characters.
- Plan for encoding changes as necessary.

  Consider differences in encoding support among operating system subcomponents. Although this product and the Java platform are based on Unicode encoding, it is not always possible to run applications in a purely Unicode environment.
- Set the console.encoding property as necessary.

### Results

If your application produces an UnsupportedEncodingException exception, check your operating system documentation to determine if the target operating system supports the required encoding and adjust the runtime environment as needed. Use the converter.properties file as appropriate to map an unsupported character set to a supported character set. A typical converter.properties file appears below:

```
Shift_JIS=CP943C
EUC-JP=Cp33722C
EUC-JP=Cp33722C
EUC-KR=Cp970
EUC-TW=Cp964
Big5=Co950
GB2312=Cp1386
ISO-2022—KR=ISO2022KR
```

The converter.properties file implements a method for specifying a content type header field that browsers would understand (such as, SHIFT_JIS) and a writer that can output characters correctly (such as, Cp943c).

Windows

### Example

For example, on the Windows platform, the command prompt runs in a Windows code page. Not all Windows code pages are supported by the Java platform, so it is possible to get a Java exception when running a command-line program, such as wsadmin, in an unsupported code page. To avoid exceptions, use the chcp command to explicitly set the code page to an encoding that is supported by the Java platform.

- Before command-line calls, change the code page.

  For example, Arabic code page 720 is not supported by the Java platform, but the Arabic code page for Windows (Cp1256) systems is. Type `chcp 1256`
- When starting a localized application from a command prompt, set the console.encoding property.

  For Arabic, pass the following parameter: `-Dconsole.encoding=Cp1256`

## Language versions offered by this product

This product is offered in several languages, as enabled by the operating platform on which the product is installed.

WebSphere Application Server offers translations for the following languages.

- Brazilian Portuguese
- Chinese (Simplified)
- Chinese (Traditional)

- Czech
- English
- French
- German
- Hungarian
- Italian
- Japanese
- Korean
- Polish
- Romanian
- Russian
- Spanish

## Globalization: Resources for learning

Use links in this topic to find relevant supplemental information about globalization. The information resides on IBM and non-IBM Internet sites, whose sponsors control the technical accuracy of the information.

These links are provided for convenience. Often, the information is not specific to this product but is useful all or in part for understanding the product. When possible, links are provided to technical papers and IBM Redbooks® publications that supplement the broad coverage of the release documentation with in-depth examinations of particular product areas.

# Task overview: Internationalizing interface strings (localizable-text API)

This topic summarizes the steps involved in implementing message catalogs through the localizable-text API.

## About this task

This product supports the maintenance and deployment of centralized message catalogs for the output of properly formatted, language-specific (*localized*) interface strings.

## Procedure

1. Identify localizable text in your application.
2. Create the message catalogs that are necessary for the locales to be supported by your application.
3. In your application code, compose the language-specific strings for output.
4. Using an assembly tool, assemble your application code as one or more application components.
5. Prepare the localizable-text package for deployment with your localized application. In this step, you create a deployment Java archive (JAR) file.
6. Assemble the application modules and the deployment JAR file into a Java Platform, Enterprise Edition (Java EE) application.
7. Deploy and manage the application.

## Results

Your application is deployed with localized text.

# Identifying localizable text

The first step in localizing strings in an application component is identifying the best candidates for translation.

## Procedure

1. Determine which elements of the application need translating. Good candidates for localization include the following:
   - Graphical user interfaces: window titles, menus and menu items, buttons, on-screen instructions
   - Prompts in command-line interfaces
   - Application output: messages and logs
2. Assign a unique key to each element for use in message catalogs for the application. The key provides a language-neutral link between the application and language-specific strings in the message catalogs. Establishing a naming convention for keys before creating the catalogs can make writing code with these keys much more intuitive for interface programmers.

## Example

Suppose you are localizing the GUI for a banking system, and the first window contains a pull-down list to use for selecting a type of account.

The labels for the list and the account types in the list are good choices for localization. Three elements require keys: the list and two items in the list.

### What to do next

Create message catalogs for the language-specific strings.

## Creating message catalogs

Perform this task to begin the localization of strings in an application component.

### Before you begin

Identify strings that need to be localized.

### About this task

You can create a catalog as either a java.util.ResourceBundle subclass or a Java properties file. The properties-file approach is more common, because properties files can be prepared by people without programming experience and swapped without modifying the application code.

### Procedure

1. For each string that is identified for localization, add a line to the message catalog that lists the string key and value in the current language. In a properties file, each line has the following structure:

   ```
   key = string associated with the key
   ```

2. Save the catalog, giving it a locale-specific name. To enable resolution to a specific properties file, the Java API specifies naming conventions for the properties files in a resource bundle as *bundleName_localeID*.properties. Give the set of message catalogs a collective name, for example, BankingResources. For information about locale IDs that are recognized by the Java APIs, see "Resources for learning."

### Example

The following English catalog (BankingResources_en.properties) supports the labels for the list and its two list items:

```
accountString = Accounts
savingsString = Savings
checkingString = Checking
```

Do not create compound strings by concatenation (for example, combining the values of savingsString and accountString to form `Savings Accounts` in English. Success depends upon the grammar of the original language (in this case, English) and is not likely to extend to other languages.

The corresponding German catalog (BankingResources_de.properties) supports the labels as follows:

```
accountString = Konten
savingsString = Sparkonto
checkingString = Girokonto
```

### What to do next

Write code to compose the language-specific strings.

## Composing language-specific strings

Perform this task to complete the localization of strings in an application component.

### Before you begin

Create message catalogs for the language-specific strings.

## Procedure

1. In application code, create a LocalizableTextFormatter instance, passing in required localization values.
2. Set other localization values as needed for more complex situations.
3. Generate a properly formatted, language-specific string.

## What to do next

When the application is finished, deploy your application. For more information, see “Preparing the localizable-text package for deployment” on page 823.

## Localization API support

The com.ibm.websphere.i18n.localizabletext package contains classes and interfaces for localizing text.

This package makes extensive use of the internationalization features of the standard Java APIs from Sun Microsystems, including the following classes:

- java.util.Locale
- java.util.TimeZone
- java.util.ResourceBundle
- java.text.MessageFormat

For more information about the standard Java APIs, see “Globalization: Resources for learning” on page 813.

The localizable-text package wraps the Java support and extends it for efficient and simple use in a distributed environment. The primary class used by application programmers is LocalizableTextFormatter. Instances of this class are usually created in server programs, but client programs can also create them. Formatter instances are created for specific resource-bundle names and keys. Client programs that receive a LocalizableTextFormatter instance call its format method. This method uses the locale of the client application to retrieve the appropriate resource bundle and compose a locale-specific message based on the key.

For example, suppose that a distributed application supports both French and English locales; the server is using an English locale and the client, a French locale. The server creates two resource bundles, one each for English and French. When the client makes a request that triggers a message, the server creates a LocalizableTextFormatter instance that contains the name of the resource bundle and the key for the message and passes the instance back to the client.

When the client receives the LocalizableTextFormatter instance, it calls the format method of the object. By using the locale and name of the resource bundle, the format method determines the name of the resource bundle that supports the French locale and retrieves the message that corresponds to the key from the French resource bundle. Formatting of the message is transparent to the client.

In this simple example, the resource bundles reside centrally with the server. They do not have to exist with the client. Part of what the localizable-text package provides is the infrastructure to support centralized catalogs. This implementation uses an enterprise bean (a stateless session bean provided with the localizable-text package) to access the message catalogs. When the client calls the format method on the LocalizableTextFormatter instance, the following events occur:

1. The client application sets the time-zone and locale values in the LocalizableTextFormatter instance, either by passing them explicitly or through default values.
2. A LocalizableTextFormatterEJBFinder call is made to retrieve a reference to the formatter bean.
3. Information from the LocalizableTextFormatter instance, including the time zone and locale of the client, is sent to the formatting bean.
4. The formatting bean uses the name of the resource bundle, the message key, the time zone, and the locale to compose a language-specific message.

5. The formatter bean returns the formatted message to the client.
6. The formatted message is inserted into the LocalizableTextFormatter instance and returned by the format method.

A call to the format method requires at most one remote call, to contact the formatter bean. As an alternative, the LocalizableTextFormatter instance can cache formatted messages, eliminating the remote call for subsequent uses. In addition, you can set a fallback string so that the application can return a readable string even if it cannot access the appropriate message catalog.

The resource bundles can be stored locally. The localizable-text package provides a static variable that indicates whether the bundles are stored locally (LocalizableConfiguration.LOCAL) or remotely (LocalizableConfiguration.REMOTE). However, the setting of this variable applies to all applications running within the same Java virtual machine.

## LocalizableTextFormatter class

The LocalizableTextFormatter class, found in the com.ibm.websphere.i18n.localizabletext package, is the primary programming interface for using the localizable-text package. Instances of this class contain the information needed to create language-specific strings from keys and resource bundles.

The LocalizableTextFormatter class extends the java.lang.Object class and implements the following interfaces:
- java.io.Serializable
- com.ibm.websphere.i18n.localizabletext.LocalizableText
- com.ibm.websphere.i18n.localizabletext.LocalizableTextL
- com.ibm.websphere.i18n.localizabletext.LocalizableTextTZ
- com.ibm.websphere.i18n.localizabletext.LocalizableTextLTZ

### Creation and initialization of class instances

The LocalizableTextFormatter class supports the following constructors:
- LocalizableTextFormatter()
- LocalizableTextFormatter(String resourceBundleName, String patternKey, String appName)
- LocalizableTextFormatter(String resourceBundleName, String patternKey, String appName, Object[] args)

The LocalizableTextFormatter instance must have certain values, such as a resource-bundle name, a key, and the name of the formatting application. If you do not pass these values in by using the second constructor listed previously, you can set them separately by making the following calls:
- setResourceBundleName(String resourceBundleName)
- setPatternKey(String patternKey)
- setApplicationName(String appName)

You can use a fourth method, setArguments(Object[] args), to set optional localization values after construction. See “Processing of application-specific values” on page 818 at the end of this topic. For a usage example, see “Composing complex strings” on page 820.

### API for formatting text

The formatting methods in the LocalizableTextFormatter class generate a string from a set of message keys and resource bundles, based on some combination of locale and time-zone values. Each method corresponds to one of the four localizable-text interfaces implemented. The following list indicates the interface in which each formatting method is defined:
- LocalizableText.format()
- LocalizableTextL.format(java.util.Locale locale)
- LocalizableTextTZ.format(java.util.TimeZone timeZone)
- LocalizableTextLTZ.format(java.util.Locale locale, java.util.TimeZone timeZone)

The format method with no arguments uses the locale and time-zone values set as defaults for the Java virtual machine. All four methods issue LocalizableException objects as needed.

### Location of message catalogs and the appName value

Applications written with the localizable-text package can access message catalogs locally or remotely. In a distributed environment, the use of remote, centrally located message catalogs is appropriate. All clients can use the same catalogs, and maintenance of the catalogs is simplified. Local formatting is useful in test situations and appropriate under some circumstances. To support either local or remote formatting, a LocalizableTextFormatter instance must indicate the name of the formatting application.

For example, when an application formats a message by using remote catalogs, the message is actually formatted by an enterprise bean on the server. Although the localizable-text package contains the code to automate the lookup of the formatter bean and to issue a call to it, the application needs to know the name of the formatter bean. Several methods in the LocalizableTextFormatter class use a value described as *appName*, which refers to the name of the formatting application. It is not necessarily the name of the application in which the value is set.

### Caching of messages

LocalizableTextFormatter instances can optionally cache formatted messages so that they do not require reformatting when needed again. By default, caching is not enabled, but you can use a `LocalizableTextFormatter.setCacheSetting(true)` call to enable caching. When caching is enabled and the format method is called, the method determines whether the message is already formatted. If so, the cached message is returned. If the message is not found in the cache, the message is formatted and returned to the caller, and a copy of the message is cached for future use.

If caching is disabled after messages are cached, those messages remain in the cache until the cache is cleared by a call to the LocalizableTextformatter.clearCache method. You can clear the cache at any time; the cache is automatically cleared when any of the following methods is called:
- setResourceBundleName(String resourceBundleName)
- setPatternKey(String patternKey)
- setApplicationName(String appName)
- setArguments(Object[] args)

### API for providing fallback information

Under some circumstances, it can be impossible to format a message. The localizable-text package implements a fallback strategy, making it possible to get some information even if a message cannot be formatted correctly into the requested language. The LocalizableTextFormatter instance can optionally store fallback values for a message string, the time zone, and the locale. These values can be ignored unless the LocalizableTextFormatter instance issues an exception. To set fallback values, call the following methods as appropriate:
- setFallBackString(String message)
- setFallBackLocale(Locale locale)
- setFallBackTimeZone(TimeZone timeZone)

For a usage example, see “Generating localized text” on page 822.

### Processing of application-specific values

The localizable-text package provides native support for localization based on time zone and locale, but you can construct messages on the basis of other values as well. If you need to consider variables other than locale and time zone in formatting localized text, write your own formatter class.

Your formatter class can extend the LocalizableTextFormatter class or independently implement some or all of the same localizable-text interfaces. As a minimum, your class must implement the java.io.Serializable interface and at least one of the localizable-text interfaces and its corresponding format method. If your class implements more than one localizable-text interface and format method, the order of evaluation of the interfaces is as follows:

1. LocalizableTextLTZ
2. LocalizableTextL
3. LocalizableTextTZ
4. LocalizableText

As an example, the localizable-text package provides a class that reports the time and date (LocalizableTextDateTimeArgument). In that class, date and time formatting is localized in accordance with three values: locale, time zone, and style.

## Creating a formatter instance

Perform this task to set localization values for strings in an application component.

### About this task

Server programs typically create LocalizableTextFormatter instances that are sent to clients as the result of some operation; clients format the objects at the appropriate time. Less typically, client programs create LocalizableTextFormatter objects locally.

### Procedure

1. If needed for your application, write your own formatter class. For more information about implementation, see “LocalizableTextFormatter class” on page 817.
2. In application code, call the appropriate constructor for the formatter class and set required localization values. Some localization values, such as resource bundle name, key and formatting application, must be set, either through a constructor or soon after construction. Other localization values can be set only as needed. For more information about the API, see the related reference.

### Example

The following code creates a LocalizableTextFormatter instance by using the default constructor and then sets the required localization values:

```
import com.ibm.websphere.i18n.localizabletext.LocalizableException;
import com.ibm.websphere.i18n.localizabletext.LocalizableTextFormatter;
import java.util.Locale;

public void drawAccountNumberGUI(String accountType) {
   ...
   LocalizableTextFormatter ltf = new LocalizableTextFormatter();
   ltf.setPatternKey("accountNumber");
   ltf.setResourceBundleName("BankingSample.BankingResources");
   ltf.setApplicationName("BankingSample");
   ...
}
```

The line of code in boldface exploits default behavior of the Java platform. By default, the Java platform looks first for a subclass of java.util.ResourceBundle called BankingResources. When none is found, the Java platform looks for a valid properties file of the same name. In this continuing example, a properties file is found.

The application that is requesting a localized message can specify the locale and time zone for message formatting, or the application can use the default values set for the Java virtual machine.

For example, a GUI can enable users to select the language in which to display the interface. A default value must be set initially so that the GUI can be created properly when the application first starts, but users can then change the locale for the GUI to suit their needs. The following code shows how to change the locale used by an application based on the selection of a menu item:

```
import java.awt.event.ActionListener;
import java.awt.event.ActionEvent;
...
import java.util.Locale;

public void actionPerformed(ActionEvent event) {
   String action = event.getActionCommand();
   ...
   if (action.equals("en_us")) {
      applicationLocale = new Locale("en", "US");
      ...
   }
   if (action.equals("de_de")) {
      applicationLocale = new Locale("de", "DE");
      ...
   }
   if (action.equals("fr_fr")) {
      applicationLocale = new Locale("fr", "FR");
      ...
   }
   ...
}
```

For more information, see "Generating localized text."

### What to do next

Set optional localization values.

## Setting optional localization values

In addition to setting localization values that are required by the LocalizableTextFormatter interface, you can set a number of optional values in application code, either through the constructor or by calling any of several methods for that purpose.

### About this task

With optional values, you can do the following actions:

- Compose complex strings from variable substrings
- Customize the formatting of strings, considering variables other than time zone and locale

### Procedure

1. In application code, add the optional values into an array of type Object.

   ```
   Object[] arg = {new String(getAccountNumber())};
   ```

2. Pass the array into a LocalizableTextFormatter instance. You can pass the array through the appropriate constructor or call the setArguments(Object[]) method. For a usage example, see “Composing complex strings.”

   Because the array is passed by value rather than by reference, any updates to the array variable after this point are not reflected in the LocalizableTextFormatter instance unless it is reset by calling the setArguments(Object[]) method.

### What to do next

Write code to generate the localized text.

#### *Composing complex strings:*

Perform this task to insert variable substrings into a localized string.

### Before you begin

Identify strings that need to be localized.

### About this task

The localized-text package supports the substitution of variable substrings into a localized string that is retrieved from the message catalog by key.

### Procedure

1. In the message catalog, specify the location of the substitution in the string to be retrieved. Variable components are designated by braces (for example, {0}).
2. In application code, create a LocalizableTextFormatter instance, passing in an array that contains the variable value. If the variable substring must be localized, you can create a nested LocalizableTextFormatter instance and pass the instance in instead of a value.
3. Generate a localized string. When a format method is called on a formatter instance, the formatter takes each element of the array passed in the previous step and substitutes it for the placeholder with the matching index in the string that is retrieved from the message catalog. For example, the value at index 0 in the array replaces the {0} variable in the retrieved string.

### Example

The following line from an English message catalog shows a string with a single substitution:

```
successfulTransaction = The operation on account {0} was successful.
```

The same key in message catalogs for other languages has a translation of this string with the variable at the appropriate location for each language.

The following code shows the creation of a single-element argument array and the creation and use of a LocalizableTextFormatter instance:

```
public void updateAccount(String transactionType) {
   ...
   Object[] arg = {new String(this.accountNumber)};
   ...
   LocalizableTextFormatter successLTF =
      new LocalizableTextFormatter ("BankingResources",
                                    "successfulTransaction",
                                    "BankingSample",
                                    arg);
   ...
   successLTF.format(this.applicationLocale);
   ...
}
```

*Nesting formatter instances for localized substrings:*

The ability to substitute variable substrings into the strings retrieved from message catalogs adds a level of flexibility to the localizable-text package, but this capability is of limited use unless the variable value can be localized. You can localize this value by nesting LocalizableTextFormatter instances.

### Before you begin

Identify strings that need to be localized.

### Procedure

1. In the message catalog, add entries that correspond to potential values for the variable substring.
2. In application code, create a LocalizableTextFormatter instance for the variable substring, setting required localization values.
3. Create a LocalizableTextFormatter instance for the primary string, passing in an array that contains the formatter instance for the variable substring.

### Example

The following line from an English message catalog shows a string entry with two substitutions and entries to support the localizable variable at index 0 (the second variable in the string, the account number, does not need to be localized):

```
successfulTransaction = The {0} operation on account {1} was successful.
depositOpString = deposit
withdrawOpString = withdrawal
```

The following code shows the creation of the nested formatter instance and its insertion (with the account number variable) into the primary formatter instance:

```
public void updateAccount(String transactionType) {
   ...
   // Successful deposit
   LocalizableTextFormatter opLTF =
      new LocalizableTextFormatter("BankingResources",
                                   "depositOpString",
                "BankingSample");
   Object[] args = {opLTF, new String(this.accountNumber)};
   ...
   LocalizableTextFormatter successLTF =
      new LocalizableTextFormatter ("BankingResources",
                                    "successfulTransaction",
                                    "BankingSample",
                                    args);
   ...
   successLTF.format(this.applicationLocale);
   ...
}
```

## Generating localized text

Perform this task to specify the runtime formatting of localized text in an application component.

### Before you begin

Create a formatter instance and set the localization values as needed.

### Procedure

1. If needed, customize the formatting behavior.
2. In application code, call the appropriate format method.

### Example

You can provide fallback behavior for use if the appropriate message catalog is not available at formatting time.

The following code generates a localized string. If the formatting fails, the application retrieves and uses a fallback string instead of the localized string:

```
import com.ibm.websphere.i18n.localizabletext.LocalizableException;
import com.ibm.websphere.i18n.localizabletext.LocalizableTextFormatter;
import java.util.Locale;
```

```
public void drawAccountNumberGUI(String accountType){
   ...
   LocalizableTextFormatter ltf = new LocalizableTextFormatter();
   ...
   ltf.setFallBackString("Enter account number: ");
   try {
      msg = new Label(ltf.format(this.applicationLocale), Label.CENTER);
   }
   catch (LocalizableException le) {
      msg = new Label(ltf.getFallBackString(), Label.CENTER);
   }
   ...
}
```

### What to do next

When the application is finished, deploy your application. For more information, see “Preparing the localizable-text package for deployment.”

#### *Customizing the behavior of a formatting method:*

Perform this task to change the runtime formatting of localized strings in an application component.

#### About this task

You can customize formatting behavior by passing your own formatter classes into a LocalizableTextFormatter instance through an array of optional values. This action enables you to consider variables other than locale and time zone when formatting localized text.

#### Procedure

1. Write your own formatter class. For more information about implementation, see "LocalizableTextFormatter class."
2. In application code, create an instance of your formatter class as appropriate and pass it with any other optional localization values into an instance of LocalizableTextFormatter. When the LocalizableTextFormatter instance reads the instance that has been passed in, it attempts to call the format() method on the passed-in instance. The string returned is then processed with any other elements in the array.

#### Example

The localizable-text package provides an example of a user-defined class, called LocalizableTextDateTimeArgument. This class enables date and time information to be selectively formatted according to the style values defined in the java.text.DateFormat interface as well as the constants that are defined within the LocalizableTextDateTimeArgument class.

## Preparing the localizable-text package for deployment

The LocalizableTextEJBDeploy tool is used to create a deployment Java Archive (JAR) file for the localizable text service. You must deploy the enterprise bean in each enterprise application that requires support for localized text.

### Before you begin

Write code to compose the language-specific strings.

### Procedure

1. Make sure that the LocalizableTextEJBDeploy tool is included in the class path.

**transition:** In versions 6.0.x and earlier, the LocalizableTextEJBDeploy tool used to reside in the file *app_server_root*/lib/ltext.jar. It now resides in the file *app_server_root*/plugins/com.ibm.ws.runtime_1.0.0.jar.

2. Set up a working directory for the LocalizableTextEJBDeploy tool to use. You need to pass this location to the tool through a command-line interface.
3. Run the LocalizableTextEJBDeploy tool. You might be asked if you want to regenerate deployment code for the LocalizableText bean. Do not redeploy the bean; if you do, an incorrect Java Naming and Directory Interface (JNDI) name will be generated.

   To deploy the bean on multiple hosts and servers, run the tool for each host and server combination. This action generates a unique JNDI name for each deployment. After the tool is run, a deployment JAR file is located in the working directory that you specified.

## What to do next

Using an assembly tool, assemble the deployment JAR file in an enterprise application with other application components.

As part of preparing for deployment, perform the following:
- Add the resource bundles for your application to the Enterprise Archive (EAR) file as files.
- Add the location of the EAR file to the server class path for the server so that the resource bundles can be located on the virtual host and server.

The same deployment JAR file can be included in several enterprise applications.

## LocalizableTextEJBDeploy command

This topic describes the command-line syntax for the LocalizableTextEJBDeploy tool.

**transition:** In versions 6.0.x and earlier, the LocalizableTextEJBDeploy tool used to reside in the file *app_server_root*/lib/ltext.jar. It now resides in the file *app_server_root*/plugins/com.ibm.ws.runtime_1.0.0.jar.

```
LocalizableTextEJBDeploy
   -a applicationName
   -h virtualHostName
   -i installationDirectory
   -s serverName
   -w workingDirectory
```

### Parameters

The required parameters, which can be specified in any order, follow:

**applicationName**
The name of the formatting session bean. This name is used in LocalizableTextFormatter instances to specify where the actual formatting occurs. If the name cannot be resolved at run time, the format method issues an exception.

**virtualHostName**
The name of the virtual host on which the formatting session bean is deployed. This value is case-sensitive on all operating platforms.

**installationDirectory**
The location at which the application server product is installed.

**serverName**
The name of the application server. If this argument is not specified, the default server name for the product is used.

**workingDirectory**
A location for the tool to use temporarily.

# Task overview: Internationalizing application components (internationalization service)

This topic summarizes the steps involved in using the internationalization service.

## About this task

With the internationalization service, you can manage the distribution of the internationalization information, or *internationalization context*, that is necessary to support globalized Java Platform, Enterprise Edition (Java EE) application components. Supported application components also include web service client environments and web service-enabled enterprise beans.

## Procedure

1. Use the internationalization context API within application components to obtain or manage internationalization context.

   Servlet and enterprise bean business methods can use internationalization context to perform locale- and time zone-sensitive localizations. Enterprise JavaBeans (EJB) client applications, and server components that are configured to manage internationalization context must use the internationalization context API to set the context elements scoped to their invocations.

   You use the internationalization context API within Web service-enabled Java EE client programs and stateless session beans in the same manner that you would use conventional Java EE application components, with one exception. Internationalization context propagated over Web service requests contains a time zone ID, whereas conventional Remote Method Invocation/ Internet Inter-ORB Protocol (RMI/IIOP) requests propagate complete time zone information, including the raw offset, Daylight Savings Time information, and so on.
2. Assemble internationalized applications.

   The internationalization type specifies the internationalization policy that applies to a servlet or an enterprise bean and, in particular, indicates whether the application component or its hosting Java EE container manages internationalization context. Container internationalization attributes can be specified for container-managed servlet and enterprise bean business methods. These attributes tailor a policy by indicating which context the container scopes to an invocation. Configuring internationalization policies declaratively prescribes, by means of the application deployment descriptor, the distribution and management of context throughout an application.

   As you edit the deployment descriptor for assembly, you can also set the internationalization type and configure any container internationalization attributes for the servlets and enterprise beans in your application.

   You configure internationalization type and container internationalization attributes for Web service-enabled stateless session beans in the same manner as you do for conventional beans.
3. Manage the internationalization service.

   Use the administrative console to enable the service on all application servers.

   By default, the service is enabled within Java EE client environments but is disabled on application servers. You must enable the service on all application servers hosting your servlets and enterprise beans to use internationalization context.
4. Troubleshoot the internationalization service as needed.

   Use the administrative console to enable the trace service to log internationalization service messages when debugging your applications.

   The trace strings for the internationalization service follow; use both:

   ```
   com.ibm.ws.i18n.context.*=all=enabled:com.ibm.websphere.i18n.context.*=all=enabled
   ```

## Internationalization service

In a distributed client-server environment, application processes can run on different machines, configured for different locales, corresponding to different cultural conventions; they can also be located across geographical boundaries. The internationalization service can help manage your application in a globally distributed environment.

For an understanding of how differences in locale impact application development, read “Globalization” on page 809.

Java Platform, Enterprise Edition (Java EE) provides support for application components that run on computers with differing endian architecture and code sets. It does not provide dedicated support for application components that run on computers with different locales or time zones.

The internationalization service addresses the challenges posed by locale and time zone mismatch without incurring the limitations of conventional techniques. The service systematically manages the distribution of internationalization contexts across the various components of EJB applications, including client applications, enterprise beans, and servlets.

The service works by associating an internationalization context with every service request within an application. When a client-side component calls a business method, the internationalization service interposes by obtaining the internationalization context associated with the current client-side process and by attaching that context to the outgoing request. On the server side, the internationalization service again interposes by detaching the context from the incoming request and associating it with the server-side process on which the business method will run, effectively scoping the context to the business method. For HTTP requests, the caller context is constructed from the HTTP attributes and default values. The service propagates internationalization context on subsequent business method invocations in the same manner, which distributes the context of the originating request over the entire chain of business method invocations.

This basic operation of scoping and propagation is defined precisely by *internationalization context management policies*. Internationalization policies specify whether an application component or its hosting Java EE container are to manage internationalization context. For container-managed components, the policy indicates which internationalization context the container scopes to invocations on that component. Server components configured to manage internationalization context, as well as EJB clients, must use the internationalization context API to manage the internationalization context elements scoped to their invocations.

Every application component has a default policy, which can be overridden and tailored for servlets and enterprise beans at assembly time.

At run time, application components can use the internationalization context API to get any element of the internationalization contexts scoped to an invocation. To programmatically access context elements, application components first resolve an internationalization context API reference, then call the appropriate API method to access the various context elements, such as the caller locale or the invocation time zone. These elements can be used in calls to Java SDK internationalization API methods; for example, to perform localizations such as formatting messages, configuring dates, or comparing strings.

## Assembling internationalized applications

Perform this task to configure application components for deployment with the internationalization service.

### About this task

Use an assembly tool to configure internationalization in the deployment descriptors for servlets and enterprise beans.

## Procedure

1. Set the **internationalization type**.

   All servlets and enterprise beans have an internationalization type setting that specifies whether internationalization context is managed by the application component or by its hosting Java Platform, Enterprise Edition (Java EE) container during invocations of their respective life cycle and business methods. The internationalization type can be configured for all server application components except entity beans, which are container-managed only.

   By default, all server components use container-managed internationalization (CMI). The default setting suffices in most cases; when it does not, modify the internationalization type setting by completing the steps that are described in one of the following topics:
   - "Setting the internationalization type for servlets"
   - "Setting the internationalization type for enterprise beans" on page 829

2. Set the **container internationalization attribute**.

   You can associate CMI servlets, and business methods of CMI enterprise beans, with a container internationalization attribute. That attribute specifies which of three internationalization contexts (**Caller**, **Server**, or **Specified**) the container is to scope to an invocation. When running as specified, the container internationalization attribute also specifies the custom internationalization context elements.

   Named container internationalization attributes can be associated with sets of servlets or with sets of Enterprise JavaBeans (EJB) business methods. Initially, CMI servlets and business methods implicitly run as caller and do not associate with a container internationalization attribute. When the implicit behavior or an associated attribute setting is unsuitable, configure an attribute by completing the steps that are described in one of the following topics:
   - "Configuring container internationalization for servlets" on page 828
   - "Configuring container internationalization for enterprise beans" on page 829

## Setting the internationalization type for servlets

This task sets the internationalization type for a servlet within a Web module.

### Before you begin

This topic assumes that you have an assembly tool such as Rational Application Developer.

For information about assembly, refer to the documentation for your assembly tool. The steps in this topic refer to Rational Application Developer.

This topic assumes that you have started the assembly tool, configured the assembly tool for work on Java Platform, Enterprise Edition (Java EE) modules, and created or imported a dynamic Web project.

### Procedure

1. In the Java EE perspective, open the Web project for which you want to set the internationalization type.
   a. Double-click **Dynamic Web Projects**.
   b. Double-click the name of the Web project to see its contents.
   c. Double-click the deployment descriptor object.

   The Web Deployment Descriptor panel is displayed.
2. In the Web Deployment Descriptor panel, click the Servlets tab.
3. Scroll down to **WebSphere Programming Model Extensions** and then **Internationalization**.
4. From the **Servlets and JSPs** list of the Servlets panel, select the servlet for which you want to set the internationalization type.
5. Under **Internationalization**, select a value from the **Internationalization type** list. Valid values are `Application` or `Container`.
6. From the menu bar, click **File > Save**.

### Results

The internationalization type setting is assigned to the servlet.

### What to do next

If you selected container-managed internationalization, you can then set container-managed internationalization attributes for methods within the servlet. For more information, see "Configuring container internationalization for servlets."

## Configuring container internationalization for servlets

This task configures container internationalization for a servlet within a Web module.

### Before you begin

This topic assumes that you have an assembly tool such as Rational Application Developer.

For information about assembly, refer to the documentation for your assembly tool. The steps in this topic refer to Rational Application Developer.

This topic assumes that you have started the assembly tool, configured the assembly tool for work on Java Platform, Enterprise Edition (Java EE) modules, and created or imported a dynamic Web project.

You must also have set the internationalization type of one or more servlets in a Web project to `Container`.

### About this task

This procedure relates one or more servlets to a container-managed internationalization attribute.

### Procedure

1. In the Java EE perspective, open the Web project for which you want to configure container internationalization.
   a. Double-click **Dynamic Web Projects**.
   b. Double-click the name of the Web project to see its contents.
   c. Double-click the deployment descriptor object.

   The Web Deployment Descriptor panel is displayed.
2. In the Web Deployment Descriptor panel, click the Servlets tab.
3. Scroll down to **WebSphere Programming Model Extensions** and then **Internationalization**.
4. Following **Container-managed Internationalization Attribute**, set the **Run As** field by selecting `Caller`, `Server`, or `Specified`.
5. If the servlet is to be run as Specified, select an internationalization policy from the **Specified** list or define a new policy.
   a. To define an internationalization policy, click **New**. The New Specified Initialization wizard is displayed.
   b. In the **Description** field, give the policy a name.
   c. If needed, set a time zone ID and add a time zone description. If you do not find the appropriate time zone in the ID list, click **Customize** to define one relative to Greenwich Mean Time (GMT).
   d. Create at least one locale for the policy. To create a locale, click **Add**; select a language and (optional) geographic region; specify a variant as needed. Add a locale description and click **OK** to finish. The new locale is added to the **Locales** list.
   e. If more than one locale is defined for the policy, select a locale from the **Locales** list and click **Finish**. Otherwise, just click **Finish**

6. From the menu bar, click **File > Save**.

### Results

Selected servlets are now configured to run under the associated internationalization settings.

## Setting the internationalization type for enterprise beans

This task sets the internationalization type for an enterprise bean within an Enterprise JavaBeans (EJB) module.

### Before you begin

This topic assumes that you have an assembly tool such as Rational Application Developer.

For information about assembly, refer to the documentation for your assembly tool. The steps in this topic refer to Rational Application Developer.

This topic assumes that you have started the assembly tool, configured the assembly tool for work on Java Platform, Enterprise Edition (Java EE) modules, and created or imported an EJB project.

### About this task

Container-managed internationalization (CMI) is the default type; entity beans cannot be set to application-managed internationalization (AMI). Use CMI also for stateless session beans that are enabled for Web services.

### Procedure

1. In the Java EE perspective, open the EJB project for which you want to set the internationalization type.
   a. Double-click **EJB Projects**.
   b. Double-click the name of the EJB project to see its contents.
   c. Double-click the deployment descriptor object.

   The EJB Deployment Descriptor panel is displayed.
2. In the EJB Deployment Descriptor panel, click the Internationalization tab. Any enterprise beans that are already configured for AMI are displayed in the **Internationalization type** list.
3. To set the internationalization type for any other enterprise beans to AMI, click **Add** following the **Internationalization type** list. The Internationalization Type wizard opens. Only message-driven or session beans can be selected.
4. Select the beans that you want to set and click **Finish** to exit the wizard.
5. From the menu bar, click **File > Save**.

### Results

The internationalization type is assigned to the bean.

### What to do next

For beans that use container-managed internationalization, you can then set container-managed internationalization attributes. For more information, see "Configuring container internationalization for enterprise beans."

## Configuring container internationalization for enterprise beans

This task configures container internationalization for enterprise bean business methods.

## Before you begin

This topic assumes that you have an assembly tool such as Rational Application Developer.

For information about assembly, refer to the documentation for your assembly tool. The steps in this topic refer to Rational Application Developer.

This topic assumes that you have started the assembly tool, configured the assembly tool for work on Java Platform, Enterprise Edition (Java EE) modules, and created or imported an EJB project.

You must also have one or more enterprise beans set to container-managed internationalization (CMI) by default.

## About this task

This procedure relates one or more business methods to one or more container-managed internationalization (CMI) attributes. Use this procedure also for stateless session beans that are enabled for Web services.

## Procedure

1. In the Java EE perspective, open the EJB project for which you want to configure container internationalization.
   a. Double-click **EJB Projects**.
   b. Double-click the name of the EJB project to see its contents.
   c. Double-click the deployment descriptor object.

   The EJB Deployment Descriptor panel is displayed.
2. In the EJB Deployment Descriptor panel, click the Internationalization tab. Any business methods that are already configured are displayed in the **Internationalization attributes** list.
3. To configure a CMI business method, click **Add** following the **Internationalization attributes** list. The Internationalization Attributes wizard opens.
4. Set the **Run As** field by selecting `Caller`, `Server`, or `Specified`. Add a meaningful description. As a group, the CMI attribute settings comprise an internationalization policy.
   - The description appears as `Internationalization` *`description`* (*`runAsSetting`*) in the **Internationalization attributes** list when you are finished.
   - If you do not provide a description, the policy name appears as `Internationalization` (*`runAsSetting`*).

   If the bean is to be run as Specified, complete the following steps to specify the context elements that the container scopes to bean method invocations.
   a. Set a time zone ID and add a time zone description as needed. If you do not find the appropriate time zone in the ID list, click **Custom** to define one relative to Greenwich Mean Time (GMT).
   b. Set a locale. Select a language and (optional) geographic region; specify a variant as needed. Add a locale description as needed and click **OK** to finish.
5. Click **Next**.
6. Select the beans for which you want to configure method-level internationalization attributes and click **Next**.
7. Select the methods that you want to configure and click **Next**. A check box is displayed next to each method name that you select.
   - Click **Apply to All** to place a check box next to the displayed bean name.
   - Click **Select Beans** to select more beans with CMI.
8. Click **Finish** to exit the wizard.
9. From the menu bar, click **File > Save**.

### Results

The bean methods are now configured to run under the associated internationalization settings.

## Using the internationalization context API

Enterprise JavaBeans (EJB) client applications, servlets, and enterprise beans can programmatically obtain and manage internationalization context using the internationalization context API. For Web service client applications, you use the API to obtain and manage internationalization context in the same manner as for EJB clients.

### Before you begin

The java.util and com.ibm.websphere.i18n.context packages contain all of the classes necessary to use the internationalization service within an EJB application.

### Procedure

1. Gain access to the internationalization context API.

   Resolve internationalization context API references once over the life cycle of an application component, within the initialization method of that component (for example, within the init method of servlets, or within the SetXxxContext method of enterprise beans). For Web service client programs, resolve a reference to the internationalization context API during initialization. For stateless session beans enabled for Web services, resolve the reference in the setSessionContext method.
2. Access caller locales and time zones.

   Every remote invocation of an application component has an associated caller internationalization context associated with the thread that is running that invocation. A caller context is propagated by the internationalization service and middleware to the target of a request, such as an Enterprise JavaBeans (EJB) business method or servlet service method. This task also applies to Web service client programs.
3. Access invocation locales and time zones.

   Every remote invocation of a servlet service or Enterprise JavaBeans (EJB) business method has an invocation internationalization context associated with the thread that is running that invocation. Invocation context is the internationalization context under which servlet and business method implementations run; it is propagated on subsequent invocations by the internationalization service and middleware. This task also applies to Web service client programs.

### Results

The resulting components are said to use *application-managed internationalization* (AMI). For more information about AMI, see “Internationalization context: Management policies” on page 846.

### Example

Each supported application component uses the internationalization context API differently. Code examples are provided that illustrate how to use the API within each component type. Differences in API usage, as well as other coding tips, are noted in comments that precede the relevant statement blocks.

- Managing internationalization context in an EJB client program
- Managing internationalization context in a servlet
- Managing internationalization context in a session bean
- Representing internationalization context in a SOAP header

**Managing internationalization context in an EJB client program:** The following code example illustrates how to use the internationalization context API within a contained EJB client program or Web service client program.

```
//----------------------------------------
// Basic Example: J2EE EJB client.
//----------------------------------------
package examples.basic;

//----------------------------------------
// INTERNATIONALIZATION SERVICE: Imports.
//----------------------------------------
import com.ibm.websphere.i18n.context.UserInternationalization;
import com.ibm.websphere.i18n.context.Internationalization;
import com.ibm.websphere.i18n.context.InvocationInternationalization;

import javax.naming.InitialContext;
import javax.naming.Context;
import javax.naming.NamingException;
import java.util.Locale;
import java.util.SimpleTimeZone;

public class EjbClient {

  public static void main(String args[]) {

    //------------------------------------------------
    // INTERNATIONALIZATION SERVICE: API references.
    //------------------------------------------------
    UserInternationalization userI18n = null;
    Internationalization callerI18n = null;
    InvocationInternationalization invocationI18n = null;

    //------------------------------------------------
    // INTERNATIONALIZATION SERVICE: JNDI name.
    //------------------------------------------------
    final String UserI18NUrl =
        "java:comp/websphere/UserInternationalization";

    //------------------------------------------------
    // INTERNATIONALIZATION SERVICE: Resolve the API.
    //------------------------------------------------
    try {
     Context initialContext = new InitialContext();
     userI18n = (UserInternationalization)initialContext.lookup(
         UserI18NUrl);
     callerI18n = userI18n.getCallerInternationalization();
     invI18n = userI18n.getInvocationInternationalization ();
    } catch (NamingException ne) {
      log("Error: Cannot resolve UserInternationalization: Exception: " + ne);
    } catch (IllegalStateException ise) {
      log("Error: UserInternationalization is not available: " + ise);
    }
    ...

    //--------------------------------------------------------------------
    // INTERNATIONALIZATION SERVICE: Set invocation context.
    //
    // Under Application-managed Internationalization (AMI), contained EJB
    // client programs may set invocation context elements. The following
    // statements associate the supplied invocation locale and time zone
    // with the current thread. Subsequent remote bean method calls will
    // propagate these context elements.
    //--------------------------------------------------------------------
    try {
      invocationI18n.setLocale(new Locale("fr", "FR", ""));
      invocationI18n.setTimeZone("ECT");
    } catch (IllegalStateException ise) {
      log("An anomaly occurred accessing Invocation context: " + ise );
    }
    ...
```

```
    //-------------------------------------------------------------------
    // INTERNATIONALIZATION SERVICE: Get locale and time zone.
    //
    // Under AMI, contained EJB client programs can get caller and
    // invocation context elements associated with the current thread.
    // The next four statements return the invocation locale and time zone
    // associated above, and the caller locale and time zone associated
    // internally by the service. Getting a caller context element within
    // a contained client results in the default element of the JVM.
    //-------------------------------------------------------------------
    Locale invocationLocale = null;
    SimpleTimeZone invocationTimeZone = null;
    Locale callerLocale = null;
    SimpleTimeZone callerTimeZone = null;
    try {
      invocationLocale = invocationI18n.getLocale();
      invocationTimeZone =
          (SimpleTimeZone)invocationI18n.getTimeZone();
      callerLocale = callerI18n.getLocale();
      callerTimeZone = SimpleTimeZone)callerI18n.getTimeZone();
    } catch (IllegalStateException ise) {
      log("An anomaly occurred accessing I18n context: " + ise );
    }

    ...
  } // main

  ...
  void log(String s) {
    System.out.println (((s == null) ? "null" : s));
  }
} // EjbClient
```

**Managing internationalization context in a servlet:** The following code example illustrates how to use the internationalization context API within a servlet. Note comments in the init and doPost methods.

```
...
//-------------------------------------------------------------------
// INTERNATIONALIZATION SERVICE: Imports.
//-------------------------------------------------------------------
import com.ibm.websphere.i18n.context.UserInternationalization;
import com.ibm.websphere.i18n.context.Internationalization;
import com.ibm.websphere.i18n.context.InvocationInternationalization;

import javax.naming.InitialContext;
import javax.naming.Context;
import javax.naming.NamingException;
import java.util.Locale;

public class J2eeServlet extends HttpServlet {

  ...
  //-------------------------------------------------------------------
  // INTERNATIONALIZATION SERVICE: API references.
  //-------------------------------------------------------------------
  protected UserInternationalization userI18n = null;
  protected Internationalization i18n = null;
  protected InvocationInternationalization invI18n = null;

  //-------------------------------------------------------------
  // INTERNATIONALIZATION SERVICE: JNDI name.
  //-------------------------------------------------------------
  public static final String UserI18NUrl =
      "java:comp/websphere/UserInternationalization";

  protected Locale callerLocale = null;
```

```
protected Locale invocationLocale = null;

/**
 * Initialize this servlet.
 * Resolve references to the JNDI initial context and the
 * internationalization context API.
 */
public void init() throws ServletException {

  //-------------------------------------------------------------------
  // INTERNATIONALIZATION SERVICE: Resolve API.
  //
  // Under Container-managed Internationalization (CMI), servlets have
  // read-only access to invocation context elements. Attempts to set these
  // elements result in an IllegalStateException.
  //
  // Suggestion: cache all internationalization context API references
  // once, during initialization, and use them throughout the servlet
  // lifecycle.
  //-------------------------------------------------------------------
  try {
    Context initialContext = new InitialContext();
    userI18n = (UserInternationalization)initialContext.lookup(UserI18nUrl);
    callerI18n = userI18n.getCallerInternationalization();
    invI18n = userI18n.getInvocationInternationalization();
  } catch (NamingException ne) {
    throw new ServletException("Cannot resolve UserInternationalization" + ne);
  } catch (IllegalStateException ise) {
    throw new ServletException ("Error: UserInternationalization is not
       available: " + ise);
  }
  ...
} // init

/**
 * Process incoming HTTP GET requests.
 * @param request Object that encapsulates the request to the servlet
 * @param response Object that encapsulates the response from the
 *    Servlet.
 */

    HttpServletRequest  request,
    HttpServletResponse response)
  throws ServletException, IOException {
  doPost(request, response);
} // doGet

/**
 * Process incoming HTTP POST requests
 * @param request Object that encapsulates the request to
 *    the Servlet.
 * @param response Object that encapsulates the response from
 *    the Servlet.
 */
public void doPost(
    HttpServletRequest  request,
    HttpServletResponse response)
  throws ServletException, IOException {

  ...
  //-------------------------------------------------------------------
  // INTERNATIONALIZATION SERVICE: Get caller context.
  //
  // The internationalization service extracts the accept-languages
  // propagated in the HTTP request and associates them with the
  // current thread as a list of locales within the caller context.
  // These locales are accessible within HTTP Servlet service methods
```

```
    // using the caller internationalization object.
    //
    // If the incoming HTTP request does not contain accept languages,
    // the service associates the server's default locale. The service
    // always associates the GMT time zone.
    //
    //---------------------------------------------------------------------
    try {
      callerLocale = callerI18n.getLocale();   // caller locale
      // the following code enables you to get invocation locale,
      // which depends on the Internationalization policies.
      invocationLocale = invI18n.getLocale();  // invocation locale
    } catch (IllegalStateException ise) {
      log("An anomaly occurred accessing Invocation context: " + ise);
    }
    // NOTE: Browsers may propagate accept-languages that contain a
    // language code, but lack a country code, like "fr" to indicate
    // "French as spoken in France."  The following code supplies a
    // default country code in such cases.
    if (callerLocale.getCountry().equals(""))
      callerLocale = AccInfoJBean.getCompleteLocale(callerLocale);

    // Use iLocale in JDK locale-sensitive operations, etc.
    ...
  } // doPost

  ...
  void log(String s) {
    System.out.println (((s == null) ? "null" : s));
  }
} // CLASS J2eeServlet
```

**Managing internationalization context in a session bean:** This code example illustrates how to perform a localized operation using the internationalization service within a session bean or Web service-enabled session bean.

```
...
//-------------------------------------------------------------
// INTERNATIONALIZATION SERVICE: Imports.
//-------------------------------------------------------------
import com.ibm.websphere.i18n.context.UserInternationalization;
import com.ibm.websphere.i18n.context.Internationalization;
import com.ibm.websphere.i18n.context.InvocationInternationalization;

import javax.naming.InitialContext;
import javax.naming.Context;
import javax.naming.NamingException;
import java.util.Locale;

/**
 * This is a stateless Session Bean Class
 */
public class J2EESessionBean implements SessionBean {

  //-------------------------------------------------------------
  // INTERNATIONALIZATION SERVICE: API references.
  //-------------------------------------------------------------
  protected UserInternationalization        userI18n = null;
  protected InvocationInternationalization  invI18n  = null;

  //-------------------------------------------------------------
  // INTERNATIONALIZATION SERVICE: JNDI name.
  //-------------------------------------------------------------
  public static final String UserI18NUrl =
      "java:comp/websphere/UserInternationalization";
  ...
```

```
  /**
   * Obtain the appropriate internationalization interface
   * reference in this method.
   * @param ctx javax.ejb.SessionContext
   */
  public void setSessionContext(javax.ejb.SessionContext ctx) {

    //-------------------------------------------------------------
    // INTERNATIONALIZATION SERVICE: Resolve the API.
    //-------------------------------------------------------------
    try {
      Context initialContext = new InitialContext();
      userI18n = (UserInternationalization)initialContext.lookup(
          UserI18NUrl);
      invI18n = userI18n.getInvocationInternationalization();
    } catch (NamingException ne) {
      log("Error: Cannot resolve UserInternationalization: Exception: " + ne);

    } catch (IllegalStateException ise) {
      log("Error: UserInternationalization is not available: " + ise);
    }
  } // setSessionContext

 /**
  * Set up resource bundle using I18n Service
  */
  public void setResourceBundle()
  {
    Locale invLocale   = null;

    //-------------------------------------------------------------
    // INTERNATIONALIZATION SERVICE: Get invocation context.
    //-------------------------------------------------------------
    try {
      invLocale = invI18n.getLocale();
    } catch (IllegalStateException ise) {
      log ("An anomaly occurred while accessing Invocation context: " + ise );
    }
    try {
      Resources.setResourceBundle(invLocale);
      // Class Resources provides support for retrieving messages from
      // the resource bundle(s). See Currency Exchange sample source code.
    } catch (Exception e) {
      log("Error: Exception occurred while setting resource bundle: " + e);
    }
  } // setResourceBundle

  /**
   * Pass message keys to get the localized texts
   * @return java.lang.String []
   * @param key java.lang.String []
   */
  public String[] getMsgs(String[] key) {
    setResourceBundle();
    return Resources.getMsgs(key);
  }

  ...
  void log(String s) {
    System.out.println(((s == null) ? ";null" : s));
  }
} // CLASS J2EESessionBean
```

**Representing internationalization context in a SOAP header:** This code example illustrates how internationalization context is represented within the SOAP header of a Web service request.

```
<InternationalizationContext>
   <Locales>
      <Locale>
         <LanguageCode>ja</LanguageCode>
         <CountryCode>JP</CountryCode>
         <VariantCode>Nihonbushi</VariantCode>
      </Locale>
      <Locale>
         <LanguageCode>fr</LanguageCode>
         <CountryCode>FR</CountryCode>
      </Locale>
      <Locale>
         <LanguageCode>en</LanguageCode>
         <CountryCode>US</CountryCode>
      </Locale>
   </Locales>
   <TimeZoneID>JST</TimeZoneID>
</InternationalizationContext>
```

This representation is valid against the following schema:

```
<?xml version="1.0" encoding="UTF-8"?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema">
    <xsd:element name="InternationalizationContext"
                 type="InternationalizationContextType">
    </xsd:element>

    <xsd:complexType name="InternationalizationContextType">
        <xsd:sequence>
            <xsd:element name="Locales"
                         type="LocalesType">
            </xsd:element>
            <xsd:element name="TimeZoneID"
                         type="xsd:string">

                         maxOccurs="1">
            </xsd:element>
```

```
        </xsd:sequence>
    </xsd:complexType>

</xsd:schema>
```

## Gaining access to the internationalization context API

Perform this task to access the internationalization service by resolving a reference to the internationalization context API.

### About this task

Resolve internationalization context API references once over the life cycle of an application component, within the initialization method of that component (for example, within the init method of servlets, or within the SetXxxContext method of enterprise beans). For Web service client programs, resolve a reference to the internationalization context API during initialization. For stateless session beans enabled for Web services, resolve the reference in the setSessionContext method.

### Procedure

1. Resolve a reference to the UserInternationalization interface by performing a lookup on the Java Naming and Directory Interface (JNDI) name `java:comp/websphere/UserInternationalization`. For example:

```
//------------------------------------------------------------------------
// Internationalization context imports.
//------------------------------------------------------------------------
import com.ibm.websphere.i18n.context.*;
import javax.naming.*;
...

public class MyApplication {
  ...

  //------------------------------------------------------------------------
  // Resolve a reference to the UserInternationalization interface.
  //------------------------------------------------------------------------
  InitialContext initCtx = null;
  UserInternationalization userI18n = null;
  final String UserI18nUrl = "java:comp/websphere/UserInternationalization";
  try {
    initCtx = new InitialContext();
    userI18n = (UserInternationalization)initCtx.lookup(UserI18nUrl);
  }
  catch (NamingException ne) {
    // UserInternationalization URL is unavailable.
  }
```

   If the UserInternationalization object is unavailable because of an anomaly or a restriction, the JNDI lookup invocation issues a javax.naming.NameNotFoundException exception that contains the java.lang.IllegalStateException instance.

2. Use the UserInternationalization reference to create references to the CallerInternationalization or InvocationInternationalization objects, which provide access to elements of the Caller or Invocation internationalization contexts, respectively. The CallerInternationalization reference can be bound to the Internationalization interface only; the InvocationInternationalization reference can be bound to either the Internationalization or the InvocationInternationalization interfaces, depending on whether the application requires read-only or read-write access to the invocation context. For example:

```
  ...
  //------------------------------------------------------------------------
  // Resolve references to the Internationalization and
  // InvocationInternationalization interfaces.
  //------------------------------------------------------------------------
  Internationalization callerI18n = null;
  InvocationInternationalization invocationI18n = null;
```

```
try {
  callerI18n = userI18n.getCallerInternationalization();
  invocationI18n = userI18n.getInvocationInternationalization();
}
catch (IllegalStateException ise) {
  // An Internationalization interface(s) is unavailable.
}
```

## Accessing caller locales and time zones

Perform this task to access elements of the caller internationalization context.

### Before you begin

An application component must first resolve a reference to the CallerInternationalization object and then bind it to the Internationalization interface.

### About this task

Every remote invocation of an application component has an associated caller internationalization context associated with the thread that is running that invocation. A caller context is propagated by the internationalization service and middleware to the target of a request, such as an Enterprise JavaBeans (EJB) business method or servlet service method. This task also applies to Web service client programs.

### Procedure

1. Obtain the desired caller context elements.

   ```
   java.util.Locale [] myLocales  = null;
   try {
     myLocales  = callerI18n.getLocales();
   }
   catch (IllegalStateException ise) {
     // The Caller context is unavailable;
     // is the service started and enabled?
   }
   ...
   ```

   The Internationalization interface contains the following methods to get caller internationalization context elements:
   - **Locale [] getLocales()** Returns the list of caller locales that are associated with the current thread.
   - **Locale getLocale()** Returns the first in the list of caller locales that are associated with the current thread.
   - **TimeZone getTimeZone()** Returns the SimpleTimeZone caller that is associated with the current thread.

   The Internationalization interface supports read-only access to internationalization context within application components. Methods of the Internationalization interface are available to all EJB application components and are used in the same manner for each, but the method semantics vary according to the component type. For instance, when obtaining the caller locale within an EJB client application, the interface returns the default locale of the host Java virtual machine (JVM); in contrast, when obtaining caller context within a servlet service method (for example, doPost or doGet methods), the interface returns the first locale (accept-language) propagated within the corresponding HTML request. See Internationalization context for a discussion of how the service propagates internationalization context throughout an application.
2. Use the caller context elements to localize computations under a locale or time zone of the calling process.

   ```
   DateFormat df = DateFormat.getDateInstance(myLocale);
   String localizedDate = df.getDateInstance().format(aDateInstance);
   ...
   ```

## Accessing invocation locales and time zones

Perform this task to access elements of the invocation internationalization context.

## Before you begin

An application component must first resolve a reference to the InvocationInternationalization object and then bind it to the InvocationInternationalization interface of the internationalization context API.

## About this task

Every remote invocation of a servlet service or Enterprise JavaBeans (EJB) business method has an invocation internationalization context associated with the thread that is running that invocation. Invocation context is the internationalization context under which servlet and business method implementations run; it is propagated on subsequent invocations by the internationalization service and middleware. This task also applies to Web service client programs.

## Procedure

1. Obtain the desired invocation context elements.

   ```
   java.util.Locale myLocale;
   try {
     myLocale = invocationI18n.getLocale();
   }
   catch (IllegalStateException ise) {
     // The invocation context is unavailable;
     // is the service started and enabled?
   }
   ...
   ```

   The InvocationInternationalization interface contains the following methods to both get and set invocation internationalization context elements:
   - **Locale [] getLocales()**. Returns the list of invocation locales that is associated with the current thread.
   - **Locale getLocale()**. Returns the first in the list of invocation locales that is associated with the current thread.
   - **TimeZone getTimeZone()**. Returns the SimpleTimeZone invocation that is associated with the current thread.
   - **setLocales(Locale [])**. Sets the list of invocation locales that are associated with the current thread to the supplied list.
   - **setLocale(Locale)**. Sets the list of invocation locales that are associated with the current thread to a list that contains the supplied locale.
   - **setTimeZone(TimeZone)**. Sets the invocation time zone that is associated with the current thread to the supplied SimpleTimeZone.
   - **setTimeZone(String)**. Sets the invocation time zone that is associated with the current thread to a SimpleTimeZone that has the supplied ID.

   The InvocationInternationalization interface supports read and write access to invocation internationalization context within application components. However, according to internationalization context management policies, only components configured to manage internationalization context (application-managed internationalization, or AMI, components) have write access to invocation internationalization context elements. Calls to set invocation context elements within container-managed internationalization (CMI) application components result in a java.lang.IllegalStateException exception. Any differences in how application components can use InvocationInternationalization methods are explained in Internationalization context.
2. Use the invocation context elements to localize a computation under a locale or time zone of the calling process.

   ```
   DateFormat df = DateFormat.getDateInstance(myLocale);
     String localizedDate = df.getDateInstance().format(aDateInstance);
     ...
   ```

### Example

In the following code example, locale (en,GB) and simple time zone (GMT) transparently propagate on the call to the myBusinessMethod method. Server-side application components, such as `myEjb`, can use the InvocationInternationalization interface to obtain these context elements.

```
...
//--------------------------------------------------------------------
// Set the invocation context under which the business method or
// servlet will run and propagate on subsequent remote business
// method invocations.
//--------------------------------------------------------------------
try {
  invocationI18n.setLocale(new Locale("en", "GB"));
  invocationI18n.setTimeZone(SimpleTimeZone.getTimeZone("GMT"));
}
catch (IllegalStateException ise) {
  // Is the component CMI; is the service started and enabled?
}
myEjb.myBusinessMethod();
```

Within CMI application components, the Internationalization and InvocationInternationalization interfaces are semantically equivalent. You can use either of these interfaces to obtain the context associated with the thread on which that component is running. For instance, both interfaces can be used to obtain the list of locales propagated to the servlet doPost service method.

## Internationalization context API: Programming reference

Application components programmatically manage internationalization context through the UserInternationalization, Internationalization, and InvocationInternationalization interfaces in the com.ibm.websphere.i18n.context package.

The following code example introduces the internationalization context API:

```
public interface UserInternationalization {
  public Internationalization getCallerInternationalization();
  public InvocationInternationalization
  getInvocationInternationalization();
}

public interface Internationalization {
  public java.util.Locale[] getLocales();
  public java.util.Locale getLocale();
  public java.util.TimeZone getTimeZone();
}

public interface InvocationInternationalization
    extends Internationalization {
  public void setLocales(java.util.Locale[] locales);
  public void setLocale(java.util.Locale jmLocale);
  public void setTimeZone(java.util.TimeZonetimeZone);
  public void setTimeZone(String timeZoneId);
}
```

### UserInternationalization interface

The UserInternationalization interface provides factory methods for obtaining references to the CallerInternationalization and InvocationInternationalization context objects. Use these references to access elements of the caller and invocation contexts correlated to the current thread.

Methods of the UserInternationalization interface:

**Internationalization getCallerInternationalization()**

Returns a reference implementing the Internationalization interface that supports access to

elements of the caller internationalization context correlated to the current thread. If the service is disabled, this method issues an IllegalStateException exception.

**InvocationInternationalization getInvocationInternationalization()**
Returns a reference implementing the InvocationInternationalization interface. If the service is disabled, this method issues an IllegalStateException exception.

### Internationalization interface

The Internationalization interface declares methods that provide read-only access to internationalization context. Given a caller or invocation internationalization context object created with the UserInternationalization interface, bind the object to the Internationalization interface to get elements of that context type. Observe that caller internationalization context can be accessed only through this interface.

Methods of the Internationalization interface:

**Locale[] getLocales()**
Returns the chain of locales within the internationalization context (object) that is bound to the interface, provided the chain is not null; otherwise this method returns a chain of length(1) containing the default locale of the Java virtual machine (JVM).

**Locale getLocale()**
Returns the first in the chain of locales within the internationalization context (object) that is bound to the interface, provided the chain is not null; otherwise this method returns the default locale of the JVM.

**TimeZone getTimeZone()**
Returns the caller time zone (that is, the SimpleTimeZone instance) that is associated with the current thread, provided the time zone is non-null; otherwise this method returns the process time zone.

### InvocationInternationalization interface

The InvocationInternationalization interface declares methods that provide read and write access to InvocationInternationalization context. Given an invocation internationalization context object created with the UserInternationalization interface, bind the object to the InvocationInternationalization interface to get and set elements of the invocation context.

According to the container-managed internationalization (CMI) policy, all set methods, setXxx(), issue an IllegalStateException exception when called within a CMI servlet or enterprise bean.

Methods of the InvocationInternationalization interface:

**void setLocales(java.util.Locale[] locales)**
Sets the chain of locales to the supplied chain, *locales*, within the invocation internationalization context. The supplied chain can be null or have length(>= 0). When the supplied chain is null or has length(0), the service sets the chain of invocation locales to an array of length(1) containing the default locale of the JVM. Null entries can exist within the supplied locale list, for which the service substitutes the default locale of the JVM on remote invocations.

**void setLocale(java.util.Locale locale)**
Sets the chain of locales within the invocation internationalization context to an array of length(1) containing the supplied locale, *locale*. The supplied locale can be null, in which case the service instead sets the chain to an array of length(1) containing the default locale of the JVM.

**void setTimeZone(java.util.TimeZone timeZone)**
Sets the time zone within the invocation internationalization context to the supplied time zone, *time zone*. If the supplied time zone is not an exact instance of java.util.SimpleTimeZone or is null, the service sets the invocation time zone to the default time zone of the JVM instead.

**void setTimeZone(String timeZoneId)**
Sets the time zone within the invocation internationalization context to the java.util.SimpleTimeZone having the supplied ID, *timeZoneId*. If the supplied time zone ID is null or

invalid (that is, the ID is not displayed in the list of IDs returned by the java.util.TimeZone.getAvailableIds method) the service sets the invocation time zone to the simple time zone having an ID of GMT, an offset of 00:00, and otherwise invalid fields.

***Internationalization context:***

An *internationalization context* is a distributable collection of internationalization information containing an ordered list, or chain, of locales and a single time zone, where the locales and time zone are instances of the java.util.Locale and java.util.TimeZone Java SDK types, respectively. A locale chain is ordered according to the user's preference.

The internationalization service manages and makes available two varieties of internationalization context: the *caller context*, which represents the caller's localization environment, and the *invocation context*, which represents the localization environment under which a business method runs. Server application components use elements of the caller and invocation internationalization contexts to appropriately tailor locale-sensitive and time zone-sensitive computations.

The internationalization service does not support time zone types other than the java.util.SimpleTimeZone type that is found in the Java SDK. Unsupported time zone types silently map to the default time zone of the JVM when supplied to internationalization context API methods. For a complete description of the java.util.Locale, java.util.TimeZone and java.util.SimpleTimeZone types, refer the Java SDK API documentation.

**Caller context**

Caller internationalization context contains the locale chain and time zone received on incoming EJB business method and servlet service method invocations; it is the internationalization context propagated from the calling process. Use caller context elements within server application components to localize computations to the calling component. Caller context is read-only and can be accessed by all application components by using the Internationalization interface of the internationalization context API.

Caller context is computed in the following manner: On an EJB business method or servlet service method invocation, the internationalization service extracts the internationalization context from the incoming request and scopes this context to the method as the caller context. For any missing or null context element, the service inserts the corresponding default element of the JVM (for example, java.util.Locale.getDefault() or java.util.TimeZone.getDefault().) The service performs a similar insertion whenever missing or null Caller context elements are encountered on invocations of stateless session beans that are enabled for Web services.

Formally, caller context is the invocation context of the calling business method or application component.

**Invocation context**

Invocation internationalization context contains the locale chain and time zone under which EJB business methods and servlet service methods run. It is managed by either the hosting container or the application component, depending on the applicable internationalization policy. On outgoing business method requests, it is the context that propagates to the target process. Use invocation context elements to localize computations under the specified settings of the current application component.

Invocation context is computed in the following manner: On an incoming business method or servlet service method invocation, the internationalization service queries the associated context management policy. If the policy is container-managed internationalization (CMI), the container scopes the context designated by the policy to the invocation; otherwise the policy is application-managed internationalization (AMI), and the container scopes an empty context to the invocation that can be altered by the method implementation.

Application components can access invocation context elements through both the Internationalization and InvocationInternationalization interfaces of the internationalization context API. Invocation context elements can be set (overwritten) under the application-managed internationalization policy only.

On an outgoing business method request, the service obtains the currently scoped invocation context and attaches it to the request. This outgoing exported context becomes the caller context of the target invocation. When supplying invocation context elements, either for export on outgoing requests or through the API, the internationalization service always provides the most recent element set using the API; the service also supplies the corresponding default element of the JVM for any null invocation context element.

Because the internationalization context that is propagated over Web services (SOAP) requests contains a time zone ID rather than the entire state of a java.lang.SimpleTimeZone object, time zone information might be lost when a Web service-enabled client program or session bean becomes involved in remote business computation.

***Internationalization context: Propagation and scope:***

The scope of internationalization context is implicit. Every Enterprise JavaBeans (EJB) client application, servlet service method, and EJB business method call has two internationalization contexts under which it runs.

For each application component call, the container enters the caller context and the call context, as indicated by the pertinent internationalization policy, into scope before the container delegates to the actual implementation. When the implementation returns, the service removes these contexts from scope. The internationalization service supplies no programmatic mechanism for components to explicitly manage the scope of internationalization context.

The service scopes internationalization context differently with respect to application component type:
- "EJB client programs (contained)"
- "Servlets" on page 845
- "Enterprise beans" on page 845
- "Web service client programs (contained)" on page 845
- "Stateless session beans that are enabled for Web services" on page 846

Internationalization context observes by-value semantics over remote method requests. Changes to internationalization context elements that are scoped to a call do not affect the corresponding elements of the internationalization context that is scoped to the remote calling process. Also, modifications to context elements obtained using the internationalization context API do not affect the corresponding elements that are scoped to the invocation.

**EJB client programs (contained)**

Before it calls the main method of a client program, the Java EE client container introduces into scope invocation and caller internationalization some contexts that contain null elements. These contexts remain in scope throughout the life of the program. EJB client programs are the base in a chain of remote business method invocations and, technically, do not have a logical caller context. Accessing a caller context element yields the corresponding default element of the client JVM. On outgoing EJB business method requests, the internationalization service propagates the invocation context to the target process. Any unset (null) invocation context elements are replaced with the default of the JVM when exported by the internationalization context API or by outgoing requests.

**Tip:**

To propagate values other than the JVM defaults to remote business methods, EJB client programs, as well as AMI servlets or enterprise beans, must set (override) elements of the invocation context. To learn how to set invocation context elements, see “Accessing invocation locales and time zones” on page 839.

**Servlets**

On every servlet service method (doGet or doPost) invocation, the Java EE Web container introduces caller and invocation internationalization contexts into scope before delegating to the service method implementation. The caller context contains the accept-languages propagated in the HTTP servlet request, typically from a Web browser. The invocation context contains whichever context is indicated by the container internationalization attribute of the internationalization policy that is associated with the servlet. Any unset (null) invocation context elements are replaced with the default of the server JVM when exported by the internationalization context API or by outgoing requests. The caller and invocation contexts remain effective until immediately after the implementation returns, at which time the container removes them from scope.

**Enterprise beans**

On every EJB business method invocation, the Java EE EJB container introduces caller and invocation internationalization contexts into scope before delegating to the business method implementation. The caller context contains the internationalization context elements imported from the incoming IIOP request; if the incoming request lacks a particular internationalization context element, the container scopes a null element. The invocation context contains whichever context is indicated by the container internationalization attribute of the internationalization policy that is associated with the business method.

On outgoing EJB business method requests, the service propagates the invocation context to the target process. Any unset (null) invocation context elements are replaced with the default of the server JVM when exported by the internationalization context API or by outgoing requests. The caller and invocation contexts remain effective until immediately after the implementation returns, when the container removes them from scope.

Consider a simple EJB application with a Java client that calls the remote myBeanMethod bean method. On the client side, the application can use the Internationalization Service API to set invocation context elements. When the client calls myBeanMethod(), the service exports the client invocation context to the outgoing request. On the server side, the service detaches the imported context from the incoming request and scopes it to the method as its caller context; the service also scopes the invocation context to the method as indicated by the associated internationalization context management policy. The EJB container then calls the myBeanMethod method, which can use the internationalization context API to access elements of either the caller or invocation contexts. When the myBeanMethod method returns, the EJB container removes these contexts from scope.

**Web service client programs (contained)**

Before it calls the main method of a Web service client program, the client container introduces into scope both invocation and caller internationalization contexts that contain null elements. These contexts remain in scope throughout the duration of the program. Web service client programs are the base in a chain of remote business method invocations and, technically, do not have a logical caller context. Accessing a Caller context element yields the corresponding default element of the client virtual machine.

On outgoing Web service requests, the internationalization service transparently creates a SOAP header block that contains the invocation context that is associated with the current thread; the SOAP representation of invocation context is propagated through the request to the target process. Any unset (that is, null) invocation context elements are replaced with the default element of the JVM when exported by the internationalization context API or by outgoing requests. Also, because the header contains only a

time zone ID, the additional state of the time zone object (java.lang.SimpleTimeZone) of the invocation context might be lost, because it does not get propagated through the request.

**Tip:**

To propagate values other than the JVM defaults to remote business methods, Web service client programs, as well as AMI servlets or enterprise beans, must set (override) elements of the invocation context. For more information, see “Accessing invocation locales and time zones” on page 839.

**Stateless session beans that are enabled for Web services**

On every method invocation of a Web service-enabled bean, the EJB container introduces caller and invocation internationalization contexts into scope before delegating control to the business method implementation. The caller context contains the internationalization context elements that are imported from the SOAP header block of the incoming request. If the incoming request lacks a particular internationalization context element, the container introduces a null element into scope. The invocation context contains whichever context is indicated by the container internationalization attribute of the internationalization policy that is associated with the business method.

On outgoing EJB business method requests, the service propagates the invocation context to the target process. Any unset (that is, null) invocation context elements are replaced with the default element of the server JVM when exported by the internationalization context API or by outgoing requests. The caller and invocation contexts remain effective until immediately after control returns from the business method implementation, at which time the container removes them from scope.

On outgoing Web service requests, the internationalization service transparently creates a SOAP header block that contains the invocation context associated with the current thread. The SOAP representation of the invocation context is propagated through the request to the target process. Any unset (that is, null) invocation context elements are replaced with the default element of the JVM when exported by the internationalization context API or by outgoing requests.

**Thread association considerations**

The Web and EJB containers scope internationalization contexts to a method by associating the method with the thread that run the method implementation. Similarly, methods of the internationalization context API either associate context with, or obtain context associated with, the thread on which these methods run.

In cases where new threads are spawned within an application component (for instance, a user-generated thread inside the service method of a servlet, or a system-generated event handling thread in an AWT client) the internationalization contexts associated with the parent thread does not automatically transfer to the newly-spawned thread. In such instances, the service exports the default locale and time zone of the JVM on any remote business method request and on any API calls that run on the new thread.

If the default context is inappropriate, the desired invocation context elements must be explicitly associated to the new thread by using the setXxx methods of the InvocationInternationalization interface. Currently, internationalization context management policies enable invocation context to be set within EJB client programs, as well as within servlets, session beans, and message-driven beans that use application-managed internationalization.

***Internationalization context: Management policies:***

Internationalization policies prescribe how Java EE application components or their hosting containers manage internationalization context on component invocations. Two internationalization context management policies apply to all component types: Application-managed internationalization (AMI) and Container-managed internationalization (CMI).

These policies are represented in two parts:
- Internationalization type
- Container internationalization attribute

The service defines a default, or implicit, internationalization policy for every application component type. At development time, assemblers can override the default policy for server component types by explicitly configuring their internationalization type, and optional container internationalization attributes. Policies configured during assembly are preserved in the deployment descriptor for the application.

All components have an internationalization type that indicates whether it is AMI or CMI; that is, whether a component is to deploy under the application-managed or the container-managed internationalization policy. Application assemblers can set the internationalization type for servlets, session beans, and message-driven beans. Entity beans are implicitly CMI and EJB clients are implicitly AMI; neither can be configured otherwise.

For CMI servlets and enterprise beans, optional container internationalization attributes can be specified to indicate which invocation internationalization context the container is to scope to service or business methods. A CMI service or business method invocation can run under the context of the caller's process, under the default context of the server JVM, or under a custom context specified in the attribute. Assemblers can specify one container internationalization attribute per disjoint set of CMI servlets within a Web module, or one Attribute per disjoint set of business methods of CMI beans within an EJB module. A container internationalization attribute can be associated with more than one method, but a method cannot be associated with more than one attribute.

When an application server launches an application, the internationalization service collects policy information from the deployment descriptor, then uses this information to construct and associate an internationalization policy to every component invocation. A policy is denoted as:

```
[<Internationalization Type>,<Container Internationalization Attribute>]
```

Several cases exist in which the deployment descriptor seems to lack policy information, for example: EJB client applications have no configurable internationalization policy settings; AMI components do not have container internationalization attributes; and you are not required to specify container internationalization attributes for CMI components. When the service cannot obtain the explicit internationalization type and container attribute settings from a well-formed deployment descriptor, it implicitly inserts the appropriate setting into the policy.

The service observes the following conventions when applying policies to invocations:
- Servlets (service) and EJB business methods lacking all internationalization policy information in the deployment descriptor implicitly run under policy `[CMI,RunAsCaller]`.
- CMI servlets and business methods lacking a container internationalization attribute in the deployment descriptor implicitly run under policy `[CMI,RunAsCaller]`.
- AMI servlets and business methods always lack container internationalization attributes in the deployment descriptor, but implicitly run under the logical policy `[AMI,RunAsServer]`.
- EJB clients always lack internationalization policy information in the deployment descriptor. By definition, EJB clients are implicitly AMI types and run under the invocation context of the JVM; they run under the logical policy `[AMI,RunAsServer]`.

For conditions other than these cited examples, such as a malformed deployment descriptor, refer to Internationalization service errors.

Internationalization policies for EJB clients and HTTP clients cannot be configured; HTTP clients do, however, run under the language priority settings of the hosting Web browser. These settings are configurable under the options dialog of most Web browsers. Refer to your Web browser documentation for details.

*Internationalization type:*

Every server application component has an *internationalization type* setting that indicates whether the invocation internationalization context is managed by the component or by the hosting Java EE container.

Server application components can be deployed to use one of two types of internationalization context management:
- Application-managed internationalization (AMI)
- Container-managed internationalization (CMI)

A server component can be deployed as AMI or CMI, but not both; CMI is the default. The setting applies to the entire component on every invocation. Entity beans use CMI only. Enterprise JavaBeans (EJB) client applications do not have an internationalization type setting; they implicitly use AMI.

**Application-managed internationalization**

Under the AMI deployment policy, component developers assume complete control over the invocation internationalization context. AMI components can use the internationalization context API to programmatically set invocation context elements.

AMI components are expected to manage invocation context. Invocations of AMI components implicitly run under the default locale and time zone of the hosting JVM. Invocation context elements not set using the API default to the corresponding elements of the JVM when accessed through the API or when exported on business methods. To export context elements other than the JVM defaults, AMI servlets, AMI enterprise beans, and EJB client applications must set (overwrite) invocation elements using the internationalization context API. Moreover, the container logically suspends the caller context that is imported on the AMI servlet lifecycle method and AMI EJB business method invocations. To continue propagating the context of the calling process, AMI servlets and enterprise beans must use the API to transfer caller context elements to the invocation context.

Specify AMI for server components that have internationalization context management requirements that are not supported by container-managed internationalization (CMI).

**Container-managed internationalization**

CMI is the preferred internationalization context management policy for server application components; it is also the default policy. Under CMI, the internationalization service collaborates with the Web and EJB containers to set the invocation internationalization context for servlets and enterprise beans. The service sets invocation context according to the container internationalization attribute of the policy that is associated with a servlet (service method) or an EJB business method.

A CMI policy has a container internationalization attribute that indicates which internationalization context the container is to scope to an invocation. For details, see Container internationalization attributes. By default, invocations of CMI components run under the caller's internationalization context; or rather, they adhere to the implicit policy `[CMI,RunasCaller]` whenever the servlet or business is not associated with an attribute in the deployment descriptor. For complete details, see Internationalization context: Management policies.

Methods within CMI components can obtain elements of the invocation context using the internationalization context API, but cannot set them. Any attempt to set invocation context elements within CMI components results in a java.lang.IllegalStateException exception.

Specify container-managed internationalization for server application components that require standard internationalization context management. Then specify the container internationalization attributes for CMI servlets and for business methods of CMI enterprise beans that you do not want to run under the caller's internationalization context.

*Container internationalization attributes:*

The internationalization policy of every CMI servlet and EJB business method has a *container internationalization attribute* that specifies which internationalization context the container is to scope to its invocation.

The container internationalization attribute has three main fields:
- Run as
- Locales
- Time zone ID

As a convenience, you can create named container internationalization attributes and associate them to the following subsets:
- CMI servlets within a Web module
- Business methods of CMI enterprise beans within an Enterprise JavaBeans (EJB) module
- Business methods of Web service-enabled session beans. In the following descriptions, the term *supported enterprise bean* refers to both CMI enterprise beans and Web service-enabled session beans.

**Run-as field**

The **Run-as** field specifies one of three types of invocation context that a container can scope to a method. For servlet service and EJB business methods, the container constructs the invocation internationalization context according to the **Run as** field setting and associates this context to the current thread before delegating to the method implementation.

By default, invocations of servlet service methods and EJB business methods implicitly run as caller (`RunAsCaller`) unless the **Run as** field of a policy attribute specifies otherwise. EJB client applications and AMI server components always run as server (`RunAsServer`).

You can specify the following invocation context types with the **Run as** field are:

**Caller** The container calls the method under the internationalization context of the calling process. For any missing context element, the container supplies the corresponding default context element of the Java virtual machine (JVM). Select run as caller when you want the invocation to run under the invocation context of the calling process.

**Server**
The container calls the method under the default locale and time zone of the JVM. Select run as server when you want the invocation to run under the invocation context of the JVM.

**Specified**
The container calls the method under the internationalization context specified in the attribute. Select run as specified when you want the invocation to run under the custom invocation context that is specified in the policy; then provide the custom context elements by completing the Locales and Time zone ID fields.

**Remember:** Java Message Service (JMS) messages do not contain internationalization context. Although container-managed message-driven beans can be configured to run as caller, the container associates the default elements of the server process when calling the onMessage method of any message-driven bean that is configured as `[CMI, RunAsCaller]`. You can also configure the **Run as** field for Web service business methods.

**Locales field**

The **Locales** field specifies an ordered list of locales that the container scopes to an invocation. A locale represents a specific geographical, cultural, or political region and contains three fields:
- **Language code**. Ideally, language code is one of the lower-case, two-character codes that are defined by the ISO 639 standard; however, language code is not restricted to ISO codes and is not a required field. A valid locale must specify a language code if it does not specify a country code.

- **Country code**. Ideally, country code is one of the upper-case, two-character codes that are defined by the ISO 3166 standard; however, country code is not restricted to ISO codes and is not a required field. A valid locale must specify a country code if it does not specify a language code.
- **Variant**. Variant is a vendor-specific code. Variant is not a required field and serves only to supplement the language and country code fields according to application- or platform-specific requirements.

A valid locale must specify at least a language code or a country code; the variant is always optional. The first locale of the list is returned when accessing invocation context using the getLocale method of the internationalization context API.

#### Time zone ID field

The **Time zone ID** field specifies an abbreviated identifier for a time zone that the container scopes to an invocation. You can also configure the **Time zone ID** field for Web service business methods.

A time zone represents a temporal offset and computes daylight savings information. A valid ID indicates any time zone supported by the java.util.TimeZone type. Specifically, a valid ID is any of the IDs that appear in the list of time zone IDs returned by method java.util.TimeZone.getAvailableIds(), or a custom ID having the form `GMT[+|-]hh[[:]mm]`; for example, `America/Los_Angeles`, `GMT-08:00` are valid time zone IDs.

## Administering the internationalization service

To use internationalization context in an Enterprise JavaBeans (EJB) application, the internationalization service must be enabled in the runtime environments for all server-side components (servlets and enterprise beans, including session beans enabled for Web service usage) as well as all client-side components (EJB client applications and Web service clients).

### About this task

If you do not require the internationalization service, do not enable it. Leaving the service disabled prevents any possible performance degradation incurred by the implicit distribution of internationalization resources.

The internationalization service cannot be enabled for HTTP clients, because support for internationalization in that case is provided by the browser, not by the application server.

### Procedure

- Enable or disable the internationalization service for servlets and enterprise beans. By default, the service is disabled for server-side components within the application server. You enable the service by using either the administrative console or the wsadmin tool.
- Enable or disable the internationalization service for EJB clients. By default, the service is disabled within the client container. You enable the service by using the launchClient tool.

### Enabling the internationalization service for servlets and enterprise beans

Perform this task to enable the internationalization service in the application server runtime environment.

#### About this task

Any servlet or enterprise bean can use internationalization context if the internationalization service is enabled within the hosting application server instance.

#### Procedure

1. Start the administrative console.
2. Click **Servers** > **Application servers** > ***server_name*** > **Container services** > **Internationalization service**.

3. Enable the internationalization service.
   a. If not already selected, select the **Enable service at server startup** check box.
   b. Click **OK**.

### Results

When you select the **Enable service at server startup** setting, the application server automatically initializes and starts the internationalization service whenever the server starts. If you change this setting, be sure to restart the application server for the new setting to take effect.

To disable the service, clear the **Enable service at server startup** check box. In this case, the internationalization service is initialized but not started when the application server starts.

### Example

Alternatively, the internationalization service can be enabled from the command line by using the wsadmin tool. Start the wsadmin tool and enter the following commands:

```
set x [$AdminConfig list I18NService]
$AdminConfig modify $x { { enable true } }
$AdminConfig save
exit
```

### What to do next

If you enable or disable the internationalization service, be sure to stop and then restart the application server for the new setting to take effect.

## Enabling the internationalization service for EJB clients

By default, the internationalization service is disabled for use within Enterprise JavaBeans (EJB) and Web-service enabled client applications. You must enable the service for client applications as well as for all server instances in the runtime environment.

### Procedure

Enable the service.
When calling the launchClient tool, include the argument `-CCDI18NService.enable=true` or `-CCDI18NService.enable=yes`.

## Internationalization service settings

Use this page to enable or disable the internationalization service. The internationalization service manages the implicit propagation and scoping of locale and time zone information, called *internationalization context*, within application components. When the service is enabled, application components can use the internationalization context API to programmatically manage locale and time zone information. In turn, components can use that locale and time zone information with the Java Platform, Standard Edition (JSE) Internationalization API to perform localizations. If internationalization support is not required on the server, disabling the service can improve performance.

To view this administrative console page, click **Servers > Server Types > WebSphere application servers >** *server_name*. Then, under Container Settings, click **Container Services > Internationalization Service**.

***Enable service at server startup:***

Specifies whether the server attempts to start the internationalization service.

**Default** Cleared

**Range** Valid values are Selected or Cleared

More information about valid values follows:

**Selected**
When the application server starts, it attempts to start the internationalization service automatically.

**Cleared**
The server does not try to start the internationalization service.

To enable the internationalization service for applications on this server, the system administrator must select this property and then restart the server.

## Internationalization service errors

Certain conditions might cause the internationalization service not to start, to issue java.lang.IllegalStateException exceptions while an application is running, or to exercise default behaviors.

The java.lang.IllegalStateException exception indicates one of the following things:

- An application component attempted an operation that is not supported by the internationalization programming model.

  The IllegalStateException exception is issued whenever a server application component whose internationalization type is set to container-managed internationalization (CMI) attempts to set invocation context. This behavior is a violation of the CMI policy, under which servlets and enterprise beans cannot modify their invocation internationalization context.
- An anomaly occurred that disabled the service.

  For instance, if the internationalization service is not properly initialized, the Java Naming and Directory Interface (JNDI) lookup on the UserInternationalization URL attribute issues a javax.naming.NameNotFoundException exception that contains an IllegalStateException instance.

The following conditions can occur while your internationalized application is running. These conditions might cause the internationalization service not to start, to issue IllegalStateException exceptions, or to exercise default behaviors:

- “The service is disabled ”
- “The service is not started” on page 853
- “Invalid context element” on page 854
- “Missing context element” on page 854
- “Invalid policy” on page 854
- “Missing policy” on page 854

If you encounter unexpected or exceptional behavior, the problem is likely related to one of these conditions. You need to examine the trace log to investigate these conditions, which requires that you configure the diagnostic trace service to generate messages about internationalization service function.

The trace strings for the internationalization service follow; use both:

```
com.ibm.ws.i18n.context.*=all=enabled:com.ibm.websphere.i18n.context.*=all=enabled
```

### The service is disabled

The internationalization service is not initialized when the startup setting is cleared. The service generates a message that indicates whether it is enabled or disabled. Applications cannot access the internationalization API when the service is disabled. If an application attempts a JNDI lookup to obtain the UserInternationalization reference, the lookup fails with a NamingException exception, indicating that the reference cannot be found. In addition, the service does not scope (propagate) internationalization context on incoming (outgoing) business method calls.

## The service is not started

The internationalization service is operational whenever it is in the STARTED state. For example, if an application attempts to access internationalization context and the service is not started, the API issues an IllegalStateException exception. In addition, the service does not provide runtime support for servlets and enterprise beans.

As an application server progresses through its life cycle, it initializes, starts, stops, and terminates (destroys) the internationalization service. If an anomaly occurs during initialization, the service does not start. After the service is started, its state can change to BLOCKED in the event that a serious error occurs. The service generates a message for every state change.

If a trace message indicates that the service is not STARTED, examine previous messages to determine the problem. For instance, the internationalization service does not start if the activity service is unavailable and a message is displayed to that effect during initialization of the internationalization service.

During startup, the following messages indicate potential configuration or runtime problems:

**No ORB support**

The service cannot obtain an instance of the object request broker (ORB). This condition is a fatal error. Examine the `SystemErr.log` and `SystemOut.log` files for information.

**Note:** This topic references one or more of the application server log files. Beginning in WebSphere Application Server Version 8.0 you can configure the server to use the High Performance Extensible Logging (HPEL) log and trace infrastructure instead of using `SystemOut.log` , `SystemErr.log`, `trace.log`, and `activity.log` files or native z/OS logging facilities. If you are using HPEL, you can access all of your log and trace information using the LogViewer command-line tool from your server profile bin directory. See the information about using HPEL to troubleshoot applications for more information on using HPEL.

**No TCM support**

The service cannot obtain an instance of its thread context manager (TCM). This condition is a fatal error. Examine the `SystemErr.log` and `SystemOut.log` files for information.

**No IIOP (activity service) support**

The service cannot register with the activity service. This condition is a fatal error. The internationalization service cannot propagate or receive context on Internet Inter-ORB Protocol (IIOP) requests without activity service support. Examine the `SystemErr.log` and `SystemOut.log` files for information.

**No AsynchBeans support**

The service cannot register into the asynchronous beans environment. This warning indicates that the asynchronous beans environment cannot support internationalization context.

**No EJB container support**

The service cannot register with the Enterprise JavaBeans (EJB) container. This warning indicates that the internationalization service cannot support enterprise beans. Without EJB container support, internationalization contexts do not scope properly to EJB business methods. Review the trace log for any EJB container-related error conditions.

**No Web container support**

The service cannot register with the Web container. This warning indicates that the internationalization service cannot support servlets and JavaServer Page (JSP) files. Without Web container support, internationalization contexts do not scope properly to servlet service methods. Review the trace log for any Web container-related error conditions.

**No Metadata support**

The service cannot register with the metadata service. This warning indicates that the internationalization service cannot process the internationalization policies within application deployment descriptors. Without metadata support, the service associates the default internationalization context management policy, [CMI, RunAsCaller], to every servlet lifecycle method and enterprise bean business method invocation. Review the trace log for any metadata service-related error conditions.

**No JNDI (Naming service) support**
The service cannot bind the UserInternationalization object into the namespace. This condition is a fatal error. Application components are unable to access internationalization context API references, and are therefore unable to access internationalization context elements. Review the trace log for any Naming (JNDI) service-related error conditions.

**No API support**
The service cannot obtain an instance of an internationalization context API object. This condition is a fatal error. Application components are unable to access internationalization context API references, and are therefore unable to access internationalization context elements.

### Invalid context element

The service detected an invalid internationalization context element. For example, the internationalization service does not support TimeZone instances of a type other than java.util.SimpleTimeZone. If the service encounters an unusable element, it logs a message and substitutes the corresponding default element of the JVM.

### Missing context element

The service detected a missing internationalization context element. Incoming requests (for example, from application servers that do not support the internationalization service) lack internationalization context. When the service attempts to access a caller internationalization context element (which does not exist in this case), the service logs a message and substitutes the corresponding default element of the Java virtual machine (JVM).

Whenever possible, enable the internationalization service within all clients and hosting application servers that comprise an internationalized enterprise application. Read more information about Administering the internationalization service in the *Administering applications and their environment* PDF book.

### Invalid policy

The internationalization service detected a malformed internationalization policy in the application deployment descriptor. The service replaces the malformed attribute with the appropriate default. For instance, if the internationalization type for an entity bean is set to `Application` during the run of a servlet or EJB business method call, the service logs the inconsistency and enforces the `Container` setting instead.

Also, AMI application components do have an implicit container internationalization attribute. By default they run as server. The service silently enforces the implicit policy, `[AMI, RunAsServer]`, and logs messages to this effect.

Invalid container internationalization attributes are likely to occur when specifying the Locales and Time zone ID fields. When encountering invalid locales and time zone IDs within attributes, the service replaces each value with the corresponding default element of the JVM. Be sure to follow the guidelines provided in the *Developing and deploying applications* PDF book.

### Missing policy

The service detected a missing internationalization policy. The service replaces the missing policy with the appropriate default. For instance, if the internationalization type is missing for a servlet or enterprise bean, the service sets the attribute to Container.

Container internationalization attributes are not mandatory for CMI application components. In the event that a CMI servlet or EJB business method lacks a container internationalization attribute, the service silently enforces the implicit policy `[CMI, RunAsCaller]`.

When an application lacks internationalization policies in its deployment descriptor, or metadata support is unavailable, the service logs a message and applies the policy `[CMI, RunAsCaller]` on every servlet service method and EJB business method invocation.

Read the information in the *Developing and deploying applications* PDF book:
- Assembling internationalized applications
- Container internationalization attributes
- Internationalization type

# Chapter 14. Developing Mail, URLs, and other Java EE resources

This page provides a starting point for finding information about resources that are used by applications that are deployed on a Java Enterprise Edition (Java EE)-compliant application server. They include:

- JavaMail support for applications to send Internet mail
- URLs, for describing logical locations
- Resource environment entries, for mapping logical names to physical names
- Java DataBase Connectivity (JDBC) resources and other technology for data access (discussed elsewhere)
- Java Message Service (JMS) resources and other messaging system support (discussed elsewhere)

## Developing applications that use the JavaMail API

## Debugging mail sessions

When you debug a mail application, you can use the mail debugging feature. The mail component generates debugging information, on a per session basis, that can be used for problem determination or tuning.

### About this task

Enabling the debug mode triggers the mail component of the application server to print the following data to the standard output stream:

- interactions with the mail servers
- properties of the mail session

This output stream is redirected to the `SystemOut.log` file for the specific application server.

**Note:** This topic references one or more of the application server log files. Beginning in WebSphere Application Server Version 8.0 you can configure the server to use the High Performance Extensible Logging (HPEL) log and trace infrastructure instead of using `SystemOut.log` , `SystemErr.log`, `trace.log`, and `activity.log` files or native z/OS logging facilities. If you are using HPEL, you can access all of your log and trace information using the LogViewer command-line tool from your server profile bin directory. See the information about using HPEL to troubleshoot applications for more information on using HPEL.

### Procedure

1. Open the administrative console.
2. Click **Resources** > **Mail** > **Mail sessions** > ***mail session***.
3. Click **Enable debug mode**. Debugging is enabled for that session only.
4. Click **Apply** or **OK**.

### Example

The following example shows sample mail debugging output:

```
ResourceMgrIm I   WSVR0049I: Binding Test as mail/test

This output illustrates a connection failure to a Simple Mail Transfer Protocol (SMTP) server because a fictitious name, smtp.coldmail.com, is specified as the server name.

The following list provides tips on reading the previous sample of debugger output:

- The lines headed by `DEBUG` are printed by the mail provider at run time, while the two lines headed by *** are printed by the application server at run time.
- In the second paragraph of code, the first few lines state that some configuration files are skipped. The mail component attempts to load a number of configuration files from different locations at run time. All those files are not required. If a required file cannot be accessed, however, the mail component creates an exception. In this sample, there is no exception and the third-line announces that default providers are loaded.
- The next few lines, headed by either `Providers Listed by Class Name` or `Providers Listed by Protocols`, show the protocol providers that are loaded. The six providers that are listed are the default protocol providers that come under the built-in mail provider for the application server. If you install special service providers, and these providers are used in the current mail session, those providers are listed here with the default providers.
- The two lines headed by *** and the few lines below them are printed by the application server to show the configuration properties of the current mail session. Although these properties are listed by their internal name rather than the name you establish in the administrative console, you can easily recognize the relationships between them. For example, the mail.store.protocol property corresponds to the **Protocol** property in the **Incoming Mail Properties** section of the console panel for mail session configuration. Review the listed properties and values to verify that they correspond.
- The few lines above the exception stack show the mail activities when sending a message. First, the JavaMail API recognizes that the transport protocol is set to SMTP and that the com.sun.mail.smtp.SMTPTransport provider exists. Next, the output log displays the useEhlo and useAuth parameters, which are used by SMTP. Finally, the log shows the SMTP provider trying to connect to the smtp.coldmail.com mail server.
- The output log show the exception stack next. This data indicates that the specified mail server either does not exist or is not functioning.

## JavaMail API

The JavaMail APIs provide a framework that is platform and protocol independent for building mail client applications that are based on Java. The JavaMail APIs are generic for sending and reading mail. They require service providers, known in the application server as protocol providers, to interact with mail servers that run on pertaining protocols. For example, Simple Mail Transfer Protocol (SMTP) is a popular transport protocol for sending mail. Mail applications can connect to an SMTP server and send mail through it by using this SMTP protocol provider.

The application server supports the JavaMail API, Version 1.4. In the application server, the JavaMail API is supported in all web application components, namely:

- servlets
- JavaServer Pages (JSP) files
- enterprise beans
- application clients

In addition to service providers, the JavaMail API requires the JavaBeans Activation Framework (JAF) to handle mail content that is not plain text, including Multipurpose Internet Mail Extensions (MIME), URL pages, and file attachments.

The JavaMail APIs, the JAF, the service providers, and the protocols are shipped as part of the application server. The API and related specifications are repackaged from materials that are licensed to Sun Microsystems.

**Note:** If you are using Java 5 to run your code, you will need the JAF 1.1 package. For Java 6 and later, the JAF package is part of the run time environment.

# Chapter 15. Developing Messaging resources

This page provides a starting point for finding information about the use of asynchronous messaging resources for enterprise applications with WebSphere Application Server.

WebSphere Application Server supports asynchronous messaging based on the Java Message Service (JMS) and the Java EE Connector Architecture (JCA) specifications, which provide a common way for Java programs (clients and Java EE applications) to create, send, receive, and read asynchronous requests, as messages.

JMS support enables applications to exchange messages asynchronously with other JMS clients by using JMS destinations (queues or topics). Some messaging providers also allow WebSphere Application Server applications to use JMS support to exchange messages asynchronously with non-JMS applications; for example, WebSphere Application Server applications often need to exchange messages with WebSphere MQ applications. Applications can explicitly poll for messages from JMS destinations, or they can use message-driven beans to automatically retrieve messages from JMS destinations without explicitly polling for messages.

WebSphere Application Server supports the following messaging providers:

- The WebSphere Application Server default messaging provider (which uses service integration as the provider).
- The WebSphere MQ messaging provider (which uses your WebSphere MQ system as the provider).
- Third-party messaging providers that implement either a JCA Version 1.5 resource adapter or the ASF component of the JMS Version 1.0.2 specification.

## Programming to use asynchronous messaging

You can build enterprise applications that use Java Message Service (JMS) APIs directly to provide asynchronous messaging services. You can also use message-driven beans as asynchronous message consumers. If you are writing messaging programs that interoperate between WebSphere Application Server and WebSphere MQ, there are some environmental differences that you need to take into account.

### About this task

Enterprise applications can use JMS APIs directly to explicitly poll for messages on a JMS destination, then retrieve messages for processing by business logic beans (enterprise beans).

Message-driven beans can also be used as asynchronous message consumers. When a message arrives at the destination, the EJB container invokes the message-driven bean automatically without an application having to explicitly poll the destination.

### Procedure

- “Programming to use JMS and messaging directly” on page 862.

  Your enterprise applications can use Java Message Service (JMS) programming interfaces directly to provide messaging services, and methods that implement business logic.

  If you choose not to use JNDI to obtain configuration information for your messaging provider, for example for connection factories or destinations, you can instead use an API provided by your messaging provider to specify that configuration information programmatically.
- Chapter 17, “Programming for interoperation with WebSphere MQ,” on page 885

  There are some differences between the WebSphere Application Server environment and the WebSphere MQ environment. If you are writing messaging programs that interoperate between these two environments, you should be aware of these differences and take them into account when designing, coding and deploying your programs.

© Copyright IBM Corp. 2011

- “Programming to use message-driven beans” on page 688.

  Applications can use message-driven beans as asynchronous message consumers. You deploy a message-driven bean as a message listener for a destination. When a message arrives at the destination, the EJB container invokes the message-driven bean automatically without an application having to explicitly poll the destination.

### Asynchronous beans - WebSphere Trader sample application

The Asynchronous beans - WebSphere Trader sample application illustrates how to implement a streaming stock ticker server and client using asynchronous beans and Java Platform, Enterprise Edition (Java EE) services such as:

- Servlets
- Java Message Service (JMS)
- Session enterprise beans
- Container-managed persistence (CMP) 2.0 enterprise beans
- Message-driven beans (MDB)

This sample uses several parts to maximize the utilization of a server:

- Work - Runs Java EE context-aware code on a thread.
- Alarm - Runs Java EE context-aware code at a given time interval.
- EventSource - A method of broadcasting events to registered listeners.
- SubsystemMonitor - A thread that monitors the status of any asynchronous system and uses an EventSource method to inform registered listeners of the system status.
- WorkManager - Thread configuration and Java EE context policies that are used by various asynchronous beans parts.
- AsynchScope - A collection of alarms, subsystem monitors and other asynchronous scopes that support relationships. This collection uses a single WorkManager thread and is also an event source.
- Startup Bean - A specialized, stateful session enterprise bean that supports bootstrapping asynchronous work when the application starts.

This sample is available from the Samples section of the information center.

## Programming to use JMS and messaging directly

Your enterprise applications can use Java Message Service (JMS) programming interfaces directly to provide messaging services, and methods that implement business logic.

### About this task

WebSphere Application Server supports asynchronous messaging as a method of communication based on JMS programming interfaces. Using JMS, enterprise applications can exchange messages asynchronously with other JMS clients by using JMS destinations (queues or topics). An enterprise application can explicitly poll for messages on a destination.

If you choose not to use JNDI to obtain configuration information for your messaging provider, for example for connection factories or destinations, you can instead use an API provided by your messaging provider to specify that configuration information programmatically.

If you want to transmit messages between JMS applications and traditional WebSphere MQ applications, you must consider how the JMS message structure is mapped onto a WebSphere MQ message . This includes scenarios where you want to use WebSphere MQ to manipulate messages transmitted between two JMS applications; for example, by using WebSphere MQ as a message broker.

By default, JMS messages held on WebSphere MQ queues use an MQRFH2 header to hold some of the JMS message header information. Many traditional WebSphere MQ applications cannot process messages with these headers, and require their own characteristic headers, for example the MQWIH for WebSphere MQ Workflow applications. For more information about how the JMS message structure is mapped onto a WebSphere MQ message, see the section *Mapping JMS messages* in the WebSphere MQ information center.

## Example

This following example shows how to programmatically configure a resource for the default messaging provider.

In this example, a JMS connection to a service integration bus is created by using the API in the com.ibm.websphere.sib package. This is an alternative to using JNDI to look up administratively configured connection factories. After the connection is established, the sample program reads lines of input from the console and sends them as JMS text messages to the specified destination.

This example can be run as a thin client application, or as a stand-alone client application.

      }

    }
  }

}
```

## Designing an enterprise application to use JMS

There are many things to consider when designing an enterprise application to use the JMS APIs directly for asynchronous messaging.

### Procedure

- For messaging operations, you should write application programs that use only references to the interfaces defined in Sun's javax.jms package.

  JMS defines a generic view of messaging that maps onto the underlying transport. An enterprise application that uses JMS makes use of the following interfaces that are defined in Sun's javax.jms package:

  **Connection**
  : Provides access to the underlying transport, and is used to create Sessions.

  **Session**
  : Provides a context for producing and consuming messages, including the methods used to create MessageProducers and MessageConsumers.

  **MessageProducer**
  : Used to send messages.

  **MessageConsumer**
  : Used to receive messages.

  The generic JMS interfaces are subclassed into the following more specific versions for point-to-point and publish/subscribe behavior.

*Table 118. The point-to-point and publish/subscribe versions of JMS common interfaces. The first column of this table lists the JMS common interfaces, the second column lists the corresponding point-to-point interfaces, and the third column lists the corresponding publish/subscribe interfaces.*

| JMS common interfaces | Point-to-point interfaces | Publish/subscribe interfaces |
|---|---|---|
| ConnectionFactory | QueueConnectionFactory | TopicConnectionFactory |
| Connection | QueueConnection | TopicConnection |
| Destination | Queue | Topic |
| Session | QueueSession, | TopicSession, |
| MessageProducer | QueueSender | TopicPublisher |
| MessageConsumer | QueueReceiver,<br>QueueBrowser | TopicSubscriber |

For more information about using these JMS interfaces, see the Java Message Service Documentation and the *Using Java* section of the WebSphere MQ information center.

The section "Java Message Service (JMS) Requirements" of the J2EE specification gives a list of methods that must not be called in web and EJB containers:

```
javax.jms.Session method setMessageListener
javax.jms.Session method getMessageListener
javax.jms.Session method run
javax.jms.QueueConnection method createConnectionConsumer
javax.jms.TopicConnection method createConnectionConsumer
javax.jms.TopicConnection method createDurableConnectionConsumer
javax.jms.MessageConsumer method getMessageListener
javax.jms.MessageConsumer method setMessageListener
javax.jms.Connection setExceptionListener
javax.jms.Connection stop
javax.jms.Connection setClientID
```

This method restriction is enforced in WebSphere Application Server by throwing a javax.jms.IllegalStateException exception.

- Applications refer to JMS resources that are predefined, as administered objects, to WebSphere Application Server.

  Details of JMS resources that are used by enterprise applications are defined to WebSphere Application Server and bound into the JNDI namespace by the WebSphere administrative support. An enterprise application can retrieve these objects from the JNDI namespace and use them without needing to know anything about their implementation. This enables the underlying messaging architecture defined by the JMS resources to be changed without requiring changes to the enterprise application.

*Table 119. JMS resources for point-to-point and publish/subscribe messaging. The left hand column of this table lists the JMS resources for point-to-point messaging, and the right hand column lists the JMS resources for publish/subscribe.*

| Point-to-point | Publish/subscribe |
|---|---|
| ConnectionFactory (or QueueConnectionFactory)<br>Queue | ConnectionFactory (or TopicConnectionFactory)<br>Topic |

A connection factory is used to create connections from the JMS provider to the messaging system, and encapsulates the configuration parameters needed to create connections.

- To improve performance, the application server pools connections and sessions with the JMS provider. You have to configure the connection and session pool properties appropriately for your applications, otherwise you might not get the connection and session behavior that you want.
- Applications must not cache JMS connections, sessions, producers or consumers. WebSphere Application Server closes these objects when a bean or servlet completes, and so any attempt to use a cached object will fail with a javax.jms.IllegalStateException exception.

  To improve performance, applications can cache JMS objects that have been looked up from JNDI. For example, an EJB or servlet needs to look up a JMS ConnectionFactory only once, but it must call the

createConnection method on each instantiation. Because of the effect of pooling on connections and sessions with the JMS provider, there should be no performance impact.

- A non-durable subscriber can only be used in the same transactional context (for example, a global transaction or an unspecified transaction context) that existed when the subscriber was created.
- Using durable subscriptions with the default messaging provider. A durable subscription on a JMS topic enables a subscriber to receive a copy of all messages published to that topic, even after periods of time when the subscriber is not connected to the server. Therefore, subscriber applications can operate disconnected from the server for long periods of time, and then reconnect to the server and process messages that were published during their absence. If an application creates a durable subscription, it is added to the runtime list that administrators can display and act on through the administrative console.

  Each durable subscription is given a unique identifier, *clientID##subName* where:

  *clientID*
  : The client identifier used to associate a connection and its objects with the messages maintained for applications (as clients of the JMS provider). You should use a naming convention that helps you identify the applications, in case you have to relate durable subscriptions to the associated applications for runtime administration.

  *subName*
  : The subscription name used to uniquely identify a durable subscription within a given client identifier.

  For durable subscriptions created by message-driven beans, these values are set on the JMS activation specification. For other durable subscriptions, the client identifier is set on the JMS connection factory, and the subscription name is set by the application on the createDurableSubscriber operation.

  To create a durable subscription to a topic, an application uses the createDurableSubscriber operation defined in the JMS API:

```
public TopicSubscriber createDurableSubscriber(Topic topic,
                          java.lang.String subName,
                          java.lang.String messageSelector,
                          boolean noLocal)
                          throws JMSException
```

  **topic** The name of the JMS topic to subscribe to. This is the name of an object supporting the javax.jms.Topic interfaces, such as found by looking up a suitable JNDI entry.

  **subName**
  : The name used to identify this subscription.

  **messageSelector**
  : Only messages with properties matching the message selector expression are delivered to consumers. A value of null or an empty string indicates that all messages should be delivered.

  **noLocal**
  : If set to `true`, this parameter prevents the delivery of messages published on the same connection as the durable subscriber.

  Applications can use a two argument form of the createDurableSubscriber operation that takes only topic and subName parameters. This alternative call directly invokes the four argument version shown above, but sets messageSelector to null (so all messages are delivered) and sets noLocal to false (so messages published on the connection are delivered). For example, to create a durable subscription to the topic called myTopic, with the subscription name of mySubscription:

```
session.createDurableSubscriber(myTopic,"mySubscription");
```

  If the createDurableSubscription operation fails, it throws a JMS exception that provides a message and linked exception to give more detail about the cause of the problem.

  To delete a durable subscription, an application uses the unsubscribe operation defined in the JMS API

  In normal operation there can be at most one active (connected) subscriber for a durable subscription at a time. However, the subscriber application can be running in a cloned application server, for failover

and load balancing purposes. In this case the “one active subscriber” restriction is lifted to provide a shared durable subscription that can have multiple simultaneous consumers.

For more information about application use of durable subscriptions, see the section “Using Durable Subscriptions” in the JMS specification.

- Decide what message selectors are needed. You can use the JMS message selector mechanism to select a subset of the messages on a queue so that this subset is returned by a receive call. The selector can refer to fields in the JMS message header and fields in the message properties.
- Acting on messages received. When a message is received, you can act on it as needed by the business logic of the application. Some general JMS actions are to check that the message is of the correct type and extract the content of the message. To extract the content from the body of the message, cast from the generic Message class (which is the declared return type of the receive methods) to the more specific subclass, such as TextMessage. It is good practice always to test the message class before casting, so that unexpected errors can be handled gracefully.

  In this example, the instanceof operator is used to check that the message received is of the TextMessage type. The message content is then extracted by casting to the TextMessage subclass.

```
       if ( inMessage instanceof TextMessage )

...
            String replyString = ((TextMessage) inMessage).getText();
```

- JMS applications using the default messaging provider can access, without any restrictions, the content of messages that have been received from WebSphere Application Server Version 5 embedded messaging or WebSphere MQ.
- JMS applications can access the full set of JMS_IBM* properties. These properties are of value to JMS applications that use resources provided by the default messaging provider, the V5 default messaging provider, or the WebSphere MQ provider.

  For messages handled by WebSphere MQ, the JMS_IBM* properties are mapped to equivalent WebSphere MQ Message Descriptor (MQMD) fields. For more information about the JMS_IBM* properties and MQMD fields, see the *Using Java* section of the WebSphere MQ information center.
- JMS applications can use report messages as a form of managed request/response processing, to give remote feedback to producers on the outcome of their send operations and the fate of their messages. JMS applications can request a full range of report options using **JMS_IBM_Report_Xxxx** message properties. For more information about using JMS report messages, see “JMS report messages” on page 869.
- JMS applications can use the **JMS_IBM_Report_Discard_Msg** property to control how a request message is disposed of if it cannot be delivered to the destination queue.

  **MQRO_Dead_Letter_Queue**
  This is the default. The request message should be written to the dead letter queue.

  **MQRO_Discard**
  The request message should be discarded. This is usually used in conjunction with MQRO_Exception_With_Full_Data to return an undeliverable request message to its sender.
- Using a listener to receive messages asynchronously. In a client, not in a servlet or enterprise bean, an alternative to making calls to QueueReceiver.receive() is to register a method that is called automatically when a suitable message is available; for example:

```
...
MyClass listener =new MyClass();
queueReceiver.setMessageListener(listener);
//application continues with other application-specific behavior.
...
```

  When a message is available, it is retrieved by the onMessage() method on the listener object.

```
import javax.jms.*;
public class MyClass implements MessageListener
{
public void onMessage(Message message)
```

```
{
System.out.println("message is "+message);
//application specific processing here
...

}
}
```

For asynchronous message delivery, the application code cannot catch exceptions raised by failures to receive messages. This is because the application code does not make explicit calls to receive() methods. To cope with this situation, you can register an ExceptionListener, which is an instance of a class that implements the onException() method. When an error occurs, this method is called with the **JMSException** passed as its only parameter.

For more details about using listeners to receive messages asynchronously, see the Java Message Service Documentation.

**Note:** An alternative to developing your own JMS listener class, you can use a message-driven bean, as described in Programming with message-driven beans.

- If you want to use authentication with WebSphere MQ or the Version 5 Embedded Messaging support, you cannot have user IDs longer than 12 characters. For example, the default Windows NT user ID, **administrator**, is not valid for use with WebSphere internal messaging, because it contains 13 characters.
- The following points, as defined in the EJB specification, apply to the use of flags on create*xxx*Session calls:
  - The transacted flag passed on create*xxx*Session is ignored inside a global transaction and all work is performed as part of the transaction. Outside of a transaction the transacted flag is used and, if set to true, the application should use session.commit() and session.rollback() to control the completion of the work. In an EJB2.0 module, if the transacted flag is set to true and outside of an XA transaction, then the session is involved in the WebSphere local transaction and the unresolved action attribute of the method applies to the JMS work if it is not committed or rolled back by the application.
  - Clients cannot use Message.acknowledge() to acknowledge messages. If a value of CLIENT_ACKNOWLEDGE is passed on the create*xxx*Session call, then messages are automatically acknowledged by the application server and Message.acknowledge() is not used.
- If you want your application to use WebSphere MQ as an external JMS provider, then send messages within a container-managed transaction.

  When you use WebSphere MQ as an external JMS provider, messages sent within a user-managed transaction can arrive before the transaction commits. This occurs only when you use WebSphere MQ as an external JMS provider, and you send messages to a WebSphere MQ queue within a user-managed transaction. The message arrives on the destination queue before the transaction commits.

  The cause of this problem is that the WebSphere MQ resource manager has not been enlisted in the user-managed transaction.

  The solution is to use a container-managed transaction.

***JMS report messages:***

JMS applications can use report messages as a form of managed request/response processing, to give remote feedback to producers on the outcome of their send operations and the fate of their messages.

JMS applications can request the following types of report message by setting appropriate JMS_IBM_Report_Xxxx message properties and options. The options have the same general syntax and meaning:

**MQRO**_*report-type*
A report message of the indicated type is generated that contains the MQMD of the original message. It does not contain any message body data.

**MQRO**_*report-type*_**WITH_DATA**
A report message of the indicated type is generated that contains the MQMD, any MQ headers, and 100 bytes of body data.

**MQRO**_*report-type*_**WITH_FULL_DATA**
A report message of the indicated type is generated that contains all data from the original message.

Use the following prefix with each option: com.ibm.websphere.sib.api.jms.

For example, to request a Confirm on delivery (COD) report message with full data, the JMS application must set JMS_IBM_Report_COD to the value com.ibm.websphere.sib.api.jms.MQRO_COD_WITH_FULL_DATA.

| Type of report message | Description | JMS_IBM_Report_Xxxx message property and options |
|---|---|---|
| Exception | Send a report message if the request message cannot be put to the target queue. The exception report messages are generated when a message has been rerouted to an exception destination. | JMS_IBM_Report_Exception<br>• MQRO_EXCEPTION<br>• MQRO_EXCEPTION_WITH_DATA<br>• MQRO_EXCEPTION_WITH_FULL_DATA |
| Discard | Discard the original request message rather than sending it to an exception destination. You can use this option with the JMS_IBM_Report_Exception property set to MQRO_EXCEPTION_WITH_FULL_DATA to return an undeliverable request message to its sender. | JMS_IBM_Report_Discard_Msg<br>• TRUE<br>• FALSE |
| Expiration | Send a report message if the request message passes its expiry time. | JMS_IBM_Report_Expiration<br>• MQRO_EXPIRATION<br>• MQRO_EXPIRATION_WITH_DATA<br>• MQRO_EXPIRATION_WITH_FULL_DATA |
| Confirm on arrival (COA) | Send a report message when the request message has been put to the target queue.<br><br>For publish/subscribe messaging, the COA report message is generated only on the producers messaging engine. Therefore, such reports are relevant only to local subscriptions.<br><br>For point-to-point messaging, COA messages are generated when the message arrives at the final destination. For partitioned queues, the report message is generated only when the put operation has committed and a final destination has therefore been selected. Any With_Data or With_Full_Data report options specified are ignored; the COA report message deals only with message headers.<br><br>If a forward-routing path is used, the COA message are generated when the message arrives at the final destination in the path. | JMS_IBM_Report_COA<br>• MQRO_COA<br>• MQRO_COA_WITH_DATA<br>• MQRO_COA_WITH_FULL_DATA |

| Type of report message | Description | JMS_IBM_Report_Xxxx message property and options |
|---|---|---|
| Confirm on delivery (COD) | Send a report message when the request message has been removed from the queue or topic space by a message consumer.<br><br>For publish/subscribe messaging, the COD message is generated when all subscribers have received the request message. Therefore, there is one COD message generated for every COA. When a message is consumed by a subscriber, the reference count of the message on the topic space is reduced. When the reference count reaches zero, the message is removed from the topic space then a COD report message is generated.<br><br>For point-to-point messaging, the COD message is generated after the message has been successfully received by a consuming application. Any With_Data or With_Full_Data report options specified are ignored; the COD report message deals only with message headers. | JMS_IBM_Report_COD<br>• MQRO_COD<br>• MQRO_COD_WITH_DATA<br>• MQRO_COD_WITH_FULL_DATA |
| Positive action notification (PAN) | Ask the consumer application to send a report message when it has successfully processed the request message. | JMS_IBM_Report_PAN<br>• TRUE<br>• FALSE |
| Negative action notification (NAN) | Ask the consumer application to send a report message if it has not successfully processed the request message. | JMS_IBM_Report_NAN<br>• TRUE<br>• FALSE |

The requesting application can control other aspects of the report message as follows:

- How the message Id is generated for the report message and any reply message:

  **MQRO_New_Msg_Id**
  This the default. A new message Id is generated for the report message.

  **MQRO_Pass_Msg_Id**
  The message Id of the report message is set to the message Id of the request message.

- How the correlation Id of the report or reply message is to be set.

  **MQRO_Copy_Msg_Id_To_Correl_Id**
  This the default. the correlation Id of the report message is set to the message Id of the request message.

  **MQRO_Pass_Correl_Id**
  The correlation Id of the report message is set to the correlation Id of the request message.

For more information about report messages and the associated properties and options, see the *Report messages* section of the WebSphere MQ information center.

## Developing an enterprise application to use JMS

Use this task to develop an enterprise application to use the JMS API directly for asynchronous messaging.

## About this task

This topic gives an overview of the steps needed to develop an enterprise application (servlet or enterprise bean) to use the JMS API directly for asynchronous messaging.

This topic only describes the JMS-related case; it does not describe general enterprise application programming, which you should already be familiar with. For detailed information about these steps, and for examples of developing an enterprise application to use JMS, see the Java Message Service Documentation

Details of JMS resources that are used by enterprise applications are defined to WebSphere Application Server and bound into the JNDI namespace by the WebSphere Application Server administrative support.

To use JMS, complete the following general steps:

## Procedure

1. Import JMS packages. An enterprise application that uses JMS starts with a number of import statements for JMS, which should include at least the following statements:

   ```
   import javax.jms.*;       //JMS interfaces
   import javax.naming.*;    //Used for JNDI lookup of administered objects
   ```

2. Get an initial context:

   ```
      try     {
           ctx = new InitialContext(env);
   ...
   ```

3. Retrieve administered objects from the JNDI namespace. The InitialContext.lookup() method is used to retrieve administered objects (a JMS connection factory and JMS destinations). The following example shows how to receive a message from a queue:

   ```
          qcf = (QueueConnectionFactory)ctx.lookup( qcfName );
   ...
          inQueue = (Queue)ctx.lookup( qnameIn );
   ...
   ```

   An alternative, but less manageable, approach to obtaining administratively-defined JMS destination objects by JNDI lookup is to use the Session.createQueue(String) method or Session.createTopic(String) method. For example:

   ```
   Queue q = mySession.createQueue("Q1");
   ```

   creates a JMS Queue instance that can be used to reference the existing destination Q1.

   In its simplest form, the parameter to these create methods is the name of an existing destination. For more complex situations, applications can use a URI-based format, which allows an arbitrary number of name value pairs to be supplied to set various properties of the JMS destination object.

4. Create a connection to the messaging service provider. The connection provides access to the underlying transport, and is used to create sessions. The createQueueConnection() method on the factory object is used to create the connection.

   ```
          connection = qcf.createQueueConnection();
   ```

   The JMS specification defines that connections should be created in the stopped state. Until the connection starts, MessageConsumers that are associated with the connection cannot receive any messages. To start the connection, issue the following command:

   ```
          connection.start();
   ```

5. Create a session, for sending or receiving messages. The session provides a context for producing and consuming messages, including the methods used to create MessageProducers and MessageConsumers. The createQueueSession method is used on the connection to obtain a session. The method takes two parameters:
   - A boolean that determines whether the session is transacted.
   - A parameter that determines the acknowledge mode.

```
boolean transacted = false;
session = connection.createQueueSession( transacted,
                                         Session.AUTO_ACKNOWLEDGE);
```

In this example, the session is not transacted, and it should automatically acknowledge received messages. With these settings, a message is backed out only after a system error or if the application terminates unexpectedly.

The following points, as defined in the EJB specification, apply to these flags:

- The transacted flag passed on createQueueSession is ignored inside a global transaction and all work is performed as part of the transaction. Outside of a transaction the transacted flag is used and, if set to true, the application should use session.commit() and session.rollback() to control the completion of the work. In an EJB2.0 module, if the transacted flag is set to `true` and outside of an XA transaction, then the session is involved in the WebSphere local transaction and the unresolved action attribute of the method applies to the JMS work if it is not committed or rolled back by the application.
- Clients cannot use Message.acknowledge() to acknowledge messages. If a value of CLIENT_ACKNOWLEDGE is passed on the create*xxx*Session call, then messages are automatically acknowledged by the application server and Message.acknowledge() is not used.

6. Send a message.
   a. Create MessageProducers to create messages. For point-to-point messaging the MessageProducer is a QueueSender that is created by passing an output queue object (retrieved earlier) into the createSender method on the session. A QueueSender is usually created for a specific queue, so that all messages sent by that sender are sent to the same destination.

      ```
      QueueSender queueSender = session.createSender(inQueue);
      ```

   b. Create the message. Use the session to create an empty message and add the data passed.

      JMS provides several message types, each of which embodies some knowledge of its content. To avoid referencing the vendor-specific class names for the message types, methods are provided on the Session object for message creation.

      In this example, a text message is created from the outString property:

      ```
      TextMessage outMessage = session.createTextMessage(outString);
      ```

   c. Send the message.

      To send the message, the message is passed to the send method on the QueueSender:

      ```
      queueSender.send(outMessage);
      ```

7. Receive replies.
   a. Create a correlation ID to link the message sent with any replies. In this example, the client receives reply messages that are related to the message that it has sent, by using a provider-specific message ID in a JMSCorrelationID.

      ```
      messageID = outMessage.getJMSMessageID();
      ```

      The correlation ID is then used in a message selector, to select only messages that have that ID:

      ```
      String selector = "JMSCorrelationID = '"+messageID+"'";
      ```

   b. Create a MessageReceiver to receive messages. For point-to-point the MessageReceiver is a QueueReceiver that is created by passing an input queue object (retrieved earlier) and the message selector into the createReceiver method on the session.

      ```
      QueueReceiver queueReceiver = session.createReceiver(outQueue, selector);
      ```

   c. Retrieve the reply message. To retrieve a reply message, the receive method on the QueueReceiver is used:

      ```
      Message inMessage = queueReceiver.receive(2000);
      ```

      The parameter in the receive call is a timeout in milliseconds. This parameter defines how long the method should wait if there is no message available immediately. If you omit this parameter, the call blocks indefinitely. If you do not want any delay, use the receiveNoWait()method. In this example, the receive call returns when the message arrives, or after 2000ms, whichever is sooner.

d. Act on the message received. When a message is received, you can act on it as needed by the business logic of the client. Some general JMS actions are to check that the message is of the correct type and extract the content of the message. To extract the content from the body of the message, it is necessary to cast from the generic Message class (which is the declared return type of the receive methods) to the more specific subclass, such as TextMessage. It is good practice always to test the message class before casting, so that unexpected errors can be handled gracefully.

   In this example, the instanceof operator is used to check that the message received is of the TextMessage type. The message content is then extracted by casting to the TextMessage subclass.

```
       if ( inMessage instanceof TextMessage )

...
            String replyString = ((TextMessage) inMessage).getText();
```

8. Closing down. If the application needs to create many short-lived JMS objects at the Session level or lower, it is important to close all the JMS resources used. To do this, you call the close() method on the various classes (QueueConnection, QueueSession, QueueSender, and QueueReceiver) when the resources are no longer required.

```
       queueReceiver.close();
...
       queueSender.close();
...
       session.close();
       session = null;
...
       connection.close();
       connection = null;
```

9. Publishing and subscribing to messages. To use JMS Publish/Subscribe support instead of point-to-point messaging, the general actions are the same; for example, to create a session and connection. The exceptions are that topic resources are used instead of queue resources (such as TopicPublisher instead of QueueSender), as shown in the following example to publish a message:

```
// Creating a TopicPublisher
       TopicPublisher pub = session.createPublisher(topic);
...
       pub.publish(outMessage);
...
       // Closing TopicPublisher
       pub.close();
```

10. Handling errors Any JMS runtime errors are reported by exceptions. The majority of methods in JMS throw JMSExceptions to indicate errors. It is good programming practice to catch these exceptions and display them on a suitable output.

    Unlike normal Java exceptions, a JMSException can contain another exception embedded in it. The implementation of JMSException does not include the embedded exception in the output of its toString()method. Therefore, you must check explicitly for an embedded exception and print it out, as shown in the following example:

```
catch (JMSException je)
{
   System.out.println("JMS failed with "+je);
   Exception le = je.getLinkedException();
   if (le != null)
   {
       System.out.println("linked exception "+le);
   }
}
```

### What to do next

After you have packaged your application, you can next deploy the application into WebSphere Application Server, as described in Chapter 16, “Deploying an enterprise application to use JMS,” on page 883.

## Developing a JMS client

Use this task to develop a JMS client application to use messages to communicate with enterprise applications.

### About this task

This topic gives an overview of the steps needed to develop a JMS client application. This topic only describes the JMS-related case; it does not describe general client programming, which you should already be familiar with. For detailed information about these steps, and for examples of developing JMS clients, see the Java Message Service Documentation and the *Using Java* section of the WebSphere MQ information center.

A JMS client assumes that the JMS resources (such as a queue connection factory and queue destination) already exist. A client application can obtain suitable JMS resources either by JNDI lookup or programmatically without using JNDI.

For information about the Thin Client for JMS with WebSphere Application Server, which is an embeddable technology that provides JMS V1.1 connections to a WebSphere Application Server default messaging provider messaging engine, see ../ae/tjj_jmsthcli.dita.

For more information about developing client applications and configuring JMS resources for them, see Developing J2EE application client code and related tasks.

To use JMS, a typical JMS client program completes the following general steps. This example is based on the use of JNDI lookups to obtain JMS resources.

### Procedure

1. Import JMS packages. An enterprise application that uses JMS starts with a number of import statements for JMS; for example:

```
import javax.naming.Context;
import javax.naming.InitialContext;
import javax.rmi.PortableRemoteObject;
import javax.jms.*;
```

2. Get an initial context.

```
   try     {
        ctx = new InitialContext(env);
...
```

3. Define the parameters that the client is to use; for example, to identify the queue connection factory and to assemble a message to be sent.

```
public class JMSppSampleClient
{
  public static void main(String[] args)
  throws JMSException, Exception

  {
    String  messageID                = null;
    String  outString                = null;
    String  qcfName                  = "java:comp/env/jms/ConnectionFactory";
    String  qnameIn                  = "java:comp/env/jms/Q1";
    String  qnameOut                 = "java:comp/env/jms/Q2";
    boolean verbose                  = false;
```

```
QueueSession           session    = null;
QueueConnection        connection = null;
Context                ctx        = null;

QueueConnectionFactory qcf        = null;
Queue                  inQueue    = null;
Queue                  outQueue   = null;
```

...

4. Retrieve administered objects from the JNDI namespace. The InitialContext.lookup() method is used to retrieve administered objects (a queue connection factory and the queue destinations):

```
qcf = (QueueConnectionFactory)ctx.lookup( qcfName );
```

...

```
inQueue = (Queue)ctx.lookup( qnameIn );
outQueue = (Queue)ctx.lookup( qnameOut );
```

...

5. Create a connection to the messaging service provider. The connection provides access to the underlying transport, and is used to create sessions. The createQueueConnection() method on the factory object is used to create the connection.

```
connection = qcf.createQueueConnection();
```

   The JMS specification defines that connections should be created in the stopped state. Until the connection starts, MessageConsumers that are associated with the connection cannot receive any messages. To start the connection, issue the following command:

```
connection.start();
```

6. Create a session, for sending and receiving messages. The session provides a context for producing and consuming messages, including the methods used to create MessageProducers and MessageConsumers. The createQueueSession method is used on the connection to obtain a session. The method takes two parameters:
   - A boolean that determines whether the session is transacted.
   - A parameter that determines the acknowledge mode.

```
boolean transacted = false;
session = connection.createQueueSession( transacted,
                                         Session.AUTO_ACKNOWLEDGE);
```

   In this example, the session is not transacted, and it should automatically acknowledge received messages. With these settings, a message is backed out only after a system error or if the client application terminates unexpectedly.

7. Send the message.
   a. Create MessageProducers to create messages. For point-to-point the MessageProducer is a QueueSender that is created by passing an output queue object (retrieved earlier) into the createSender method on the session. A QueueSender is usually created for a specific queue, so that all messages sent by that sender are sent to the same destination.

```
QueueSender queueSender = session.createSender(inQueue);
```

   b. Create the message. Use the session to create an empty message and add the data passed.

      JMS provides several message types, each of which embodies some knowledge of its content. To avoid referencing the vendor-specific class names for the message types, methods are provided on the Session object for message creation.

      In this example, a text message is created from the outString property, which could be provided as an input parameter on invocation of the client program or constructed in some other way:

```
TextMessage outMessage = session.createTextMessage(outString);
```

   c. Send the message.

      To send the message, the message is passed to the send method on the QueueSender:

```
queueSender.send(outMessage);
```

8. Receive replies.

a. Create a correlation ID to link the message sent with any replies. In this example, the client receives reply messages that are related to the message that it has sent, by using a provider-specific message ID in a JMSCorrelationID.

```
messageID = outMessage.getJMSMessageID();
```

The correlation ID is then used in a message selector, to select only messages that have that ID:

```
String selector = "JMSCorrelationID = '"+messageID+"'";
```

b. Create a MessageReceiver to receive messages. For point-to-point the MessageReceiver is a QueueReceiver that is created by passing an input queue object (retrieved earlier) and the message selector into the createReceiver method on the session.

```
QueueReceiver queueReceiver = session.createReceiver(outQueue, selector);
```

c. Retrieve the reply message. To retrieve a reply message, the receive method on the QueueReceiver is used:

```
Message inMessage = queueReceiver.receive(2000);
```

The parameter in the receive call is a timeout in milliseconds. This parameter defines how long the method should wait if there is no message available immediately. If you omit this parameter, the call blocks indefinitely. If you do not want any delay, use the receiveNoWait()method. In this example, the receive call returns when the message arrives, or after 2000ms, whichever is sooner.

d. Act on the message received. When a message is received, you can act on it as needed by the business logic of the client. Some general JMS actions are to check that the message is of the correct type and extract the content of the message. To extract the content from the body of the message, cast from the generic Message class (which is the declared return type of the receive methods) to the more specific subclass, such as TextMessage. It is good practice always to test the message class before casting, so that unexpected errors can be handled gracefully.

In this example, the instanceof operator is used to check that the message received is of the TextMessage type. The message content is then extracted by casting to the TextMessage subclass.

```
if ( inMessage instanceof TextMessage )

...
      String replyString = ((TextMessage) inMessage).getText();
```

9. Closing down. If the application needs to create many short-lived JMS objects at the Session level or lower, it is important to close all the JMS resources used. To do this, you call the close() method on the various classes (QueueConnection, QueueSession, QueueSender, and QueueReceiver) when the resources are no longer required.

```
queueReceiver.close();
...
queueSender.close();
...
session.close();
session = null;
...
connection.close();
connection = null;
```

10. Publishing and subscribing messages. To use publish/subscribe support instead of point-to-point messaging, the general client actions are the same; for example, to create a session and connection. The exceptions are that topic resources are used instead of queue resources (such as TopicPublisher instead of QueueSender), as shown in the following example to publish a message:

```
// Creating a TopicPublisher
TopicPublisher pub = session.createPublisher(topic);
...
pub.publish(outMessage);
...
// Closing TopicPublisher
pub.close();
```

11. Handling errors Any JMS runtime errors are reported by exceptions. The majority of methods in JMS throw JMSExceptions to indicate errors. It is good programming practice to catch these exceptions and display them on a suitable output.

    Unlike normal Java exceptions, a JMSException can contain another exception embedded in it. The implementation of JMSException does not include the embedded exception in the output of its toString()method. Therefore, you must check explicitly for an embedded exception and print it out, as shown in the following example:

```
catch (JMSException je)
{
   System.out.println("JMS failed with "+je);
   Exception le = je.getLinkedException();
   if (le != null)
   {
       System.out.println("linked exception "+le);
   }
}
```

### What to do next

For information about running a client against a specific remote server: “Running a Java EE client application with launchClient” on page 343.

## JMS interfaces

WebSphere Application Server supports applications that use JMS 1.1 domain-independent interfaces (referred to as “common interfaces” in the JMS specification) and JMS 1.0.2 domain-specific interfaces.

With JMS 1.1, the preferred approach for implementing applications is to use common interfaces because they provide a simpler programming model than domain-specific interfaces. Also, applications can create both queues and topics in the same session and coordinate their use in the same transaction. Common interfaces are parents of domain-specific interfaces.

**Note:** Domain-specific interfaces (provided for JMS 1.0.2 in WebSphere Application Server Version 5) are supported only to provide compatibility for applications that have already been implemented to use those interfaces.

*Table 120. The point-to-point and publish/subscribe versions of JMS common interfaces. The first column of the table lists the JMS common interfaces. The second column lists the point-to-point versions of the JMS common interfaces. The third column lists the publish/subscribe versions of the JMS common interfaces.*

| JMS common interfaces | Point-to-point interfaces | Publish/subscribe interfaces |
|---|---|---|
| ConnectionFactory | QueueConnectionFactory | TopicConnectionFactory |
| Connection | QueueConnection | TopicConnection |
| Destination | Queue | Topic |
| Session | QueueSession | TopicSession, |
| MessageProducer | QueueSender | TopicPublisher |
| MessageConsumer | QueueReceiver,<br>QueueBrowser | TopicSubscriber |

For more information about JMS interfaces, see the JMS documentation at http://java.sun.com/products/jms/docs.html.

## Example: Programmatically configuring a resource for the default messaging provider

In this example, a JMS connection to a service integration bus is created by using the API in the com.ibm.websphere.sib package. This is an alternative to using JNDI to look up administratively configured

connection factories. After the connection is established, the example reads lines of input from the console and sends them as JMS text messages to the specified destination.

This example can be run as a thin client application, or as a stand-alone client application.

# Chapter 16. Deploying an enterprise application to use JMS

You can deploy an enterprise application to use JMS.

## About this task

This task description assumes that you have an .EAR file, which contains an application enterprise bean with code for JMS, that can be deployed in WebSphere Application Server.

To deploy an enterprise application to use JMS, complete the following steps:

## Procedure

1. Configure the deployment attributes for the application, as described in Assembling applications.
2. Use the WebSphere Application Server administrative console to install the application.
   This stage is a standard WebSphere Application Server task, as described in Installing applications.

© Copyright IBM Corp. 2011

# Chapter 17. Programming for interoperation with WebSphere MQ

There are some differences between the WebSphere Application Server environment and the WebSphere MQ environment. If you are writing messaging programs that interoperate between these two environments, you should be aware of these differences and take them into account when designing, coding and deploying your programs.

### Procedure

1. Learn more about the environment differences and other relevant concepts in How messages are passed between service integration and a WebSphere MQ network.
2. Read about designing programs that interoperate with WebSphere MQ in "Designing an application for interoperation with WebSphere MQ."

## Designing an application for interoperation with WebSphere MQ

To design an application to interoperate with queue managers in a WebSphere MQ network you need to first consider the differences between the two environments, then design your JMS client based on the Java EE pattern, then identify any name-handling incompatibilities between the service integration bus and WebSphere MQ environments, then define the topic mappings.

### Before you begin

Identify the WebSphere MQ queues with which your applications will interoperate. The exact names and locations can be left to the installation.

### Procedure

1. Familiarize yourself with important reference information for the two interoperating environments, WebSphere MQ and the service integration bus.

   There are three types of reference material:

   - For mapping that is unique to service integration bus messaging, see "Mapping additional MQRFH2 header fields in service integration" on page 900.
   - For mapping between WebSphere Application Server service integration bus messaging and WebSphere MQ, see How service integration converts messages to and from WebSphere MQ format and "Mapping additional MQRFH2 header fields in service integration" on page 900.
   - For the differences between the WebSphere MQ functions and the service integration bus, see "WebSphere MQ functions not supported by service integration" on page 903.

2. Design your JMS client based on the typical Java EE pattern:
   a. Use JNDI to find a ConnectionFactory object.
   b. Use JNDI to find one or more Destination objects.
   c. Use the connection factory to create a JMS Connection object.
   d. Use the JMS connection to create one or more JMS Session objects.
   e. Use a JMS session and the destinations to create the MessageProducer and MessageConsumer objects.
   f. Start delivery of messages by starting the JMS connection.

   At this point a client has the basic JMS setup needed to produce and consume messages.
3. Identify any name-handling incompatibilities between the service integration bus and WebSphere MQ environments. If necessary, identify alias requirements, so that the WebSphere MQ application can handle service integration bus destination names of greater than 48 characters. For more information, see How to address bus destinations and WebSphere MQ queues.

© Copyright IBM Corp. 2011

4. Identify any reply destinations that are used by your application and check them for name-handling incompatibilities. For more information, see “Mapping destinations to and from WebSphere MQ queues, topics, and destinations” on page 894.
5. If your application publishes messages that you want to be forwarded to WebSphere MQ brokers, work with your administrator to define appropriate topic mappings on a publish/subscribe broker profile. You must also define topic mappings for any permanent reply topics. See Reply-to topics for request-reply messaging through a WebSphere MQ link and Request-reply messaging through a WebSphere MQ link for more information.

# Mapping the message body to and from WebSphere MQ format

The WebSphere MQ message header (MQRFH2) and descriptor (MQMD) can contain information about the format of the WebSphere MQ message body. Service integration uses information contained in the MQRFH2 and MQMD when converting a message from WebSphere MQ format, and puts information into the MQRFH2 and MQMD when converting a message to WebSphere MQ format.

## Exchanging messages between JMS programs through service integration and WebSphere MQ

Usually, you do not have to be aware of conversion between message formats to exchange JMS messages between service integration and WebSphere MQ, because service integration performs the appropriate conversion automatically, including character and numeric encoding. However, you might have to learn about message conversion if your JMS applications do not behave as expected, or if your service integration configuration includes JMS programs or mediations that process messages to or from non-JMS WebSphere MQ programs.

If your service integration applications exchange MapMessage objects with WebSphere MQ applications, you might have to specify a non-default map message encoding format.

## WebSphere MQ message payload: format indications

The WebSphere MQ format message contains the following two indications of the payload format:

**MQRFH2 <mcd> folder, Msd field**

This field can contain information about the payload format. This is the “JMS format” information.

- When service integration converts a message to WebSphere MQ format, it automatically sets the appropriate value for the JMS message class.
- When service integration converts a message from WebSphere MQ format, it uses the value in this field (if there is an MQRFH2 that contains the field) to set the JMS message class.

| JMS message class | MQRFH2 <mcd> folder, Msd field (“JMS format”) |
|---|---|
| TextMessage | jms_text |
| BytesMessage | jms_bytes |
| StreamMessage | jms_stream |
| MapMessage | jms_map |
| ObjectMessage | jms_object |
| Message | jms_none |

If the “JMS format” information is not available, for example if there is no MQRFH2, service integration sets the JMS message class based on the “MQ format” (see below).

For more information about the MQRFH2 <mcd> folder, see the WebSphere MQ Using Java documentation.

### MQRFH2 (or MQMD) format field

The MQRFH2 (or the MQMD if there is no MQRFH2) format field contains information about the payload format. This is the "MQ format" information. Typically it contains `MQFMT_STRING`, which indicates that the payload is character data (and can be translated to a different codepage by WebSphere MQ), or `MQFMT_NONE`, which indicates that the payload is not character data. These values are suitable for most JMS messages, and when service integration converts a message to WebSphere MQ format it automatically sets this field to one of the following values:

| JMS message class | MQRFH2 (or MQMD) format field ("MQ format") |
|---|---|
| TextMessage | MQFMT_STRING |
| BytesMessage | MQFMT_NONE |
| StreamMessage | MQFMT_STRING |
| MapMessage | MQFMT_STRING |
| ObjectMessage | MQFMT_NONE |
| Message | MQFMT_NONE |

If your application constructs messages for a WebSphere MQ application that requires a different format value, you can override the value from the previous table by setting the `JMS_IBM_Format` property to the required value. A particular example is when the WebSphere MQ application requires an additional header (for example, the MQCIH header for a CICS bridge application). Your application constructs a BytesMessage object that contains the header followed by any other message data, then replaces the default "MQ format" (`MQFMT_NONE`) by setting the `JMS_IBM_Format` property to the appropriate value for the header (for example, `MQFMT_CICS` for an MQCIH header).

When service integration converts a message from WebSphere MQ format, it sets the `JMS_IBM_Format` property to the value in the "MQ format" field. If the "JMS format" is not available, for example if there is no MQRFH2, service integration sets the JMS message class to `TextMessage` if the "MQ format" is `MQFMT_STRING` and to `BytesMessage` otherwise.

For more information about the MQRFH2 (or MQMD) format field, see the WebSphere MQ Application Programming Reference.

## WebSphere MQ message payload: character and numeric encoding

In addition to the format field, the MQRFH2 (or the MQMD if there is no MQRFH2) contains fields that identify the character encoding and numeric encoding for the message payload.

***When service integration converts a message to WebSphere MQ format***, it automatically selects default values (UTF-8 character encoding and big-endian numeric encoding) that are suitable for most JMS messages. If your application constructs messages for a WebSphere MQ application that requires a different character or numeric encoding, you can override the character encoding value by setting the **JMS_IBM_Character_Set** property to the required coded character set ID (CCSID), or the **JMS_IBM_Encoding** property to the required numeric format, or both. For information about the values you can use for **JMS_IBM_Character_Set** and **JMS_IBM_Encoding**, see the documentation in the WebSphere MQ library.

When the JMS message has a body that is encoded as character data in WebSphere MQ (TextMessage, StreamMessage, or MapMessage), setting **JMS_IBM_Character_Set** causes service integration to convert the text to that coded character set in the WebSphere MQ message body.

When the JMS message has a body that is not character data (BytesMessage or ObjectMessage), setting **JMS_IBM_Character_Set** does not cause service integration to convert the bytes; it indicates to WebSphere MQ that any character data in the message body is already encoded using the specified

coded character set. If the value of the **JMS_IBM_Format** is a format that WebSphere MQ recognises, it can convert that character data to the coded character set that the receiving application requires.

***When service integration converts a message from WebSphere MQ format***, it sets the **JMS_IBM_Character_Set** and **JMS_IBM_Encoding** properties from the fields in the MQRFH2 (or the MQMD if there is no MQRFH2). If the JMS message is a TextMessage, StreamMessage, MapMessage, or ObjectMessage, your application makes no use of the values of the **JMS_IBM_Character_Set** and **JMS_IBM_Encoding** properties. If the JMS message is a BytesMessage, then the body of the JMS message is binary data. In this case, your application must be aware of the values of the **JMS_IBM_Character_Set** and **JMS_IBM_Encoding** properties, because they indicate the encoding of any character data or numeric data that is embedded within the binary data of the message.

## Mapping the message header fields and properties to and from WebSphere MQ format

When service integration converts a message to WebSphere MQ format, it sets fields in the MQMD and the MQRFH2 based on the service integration message header fields and properties; these include JMS message header fields and properties applicable to the message. When service integration converts a message from WebSphere MQ format, it sets the service integration message header fields and properties from the MQMD and the MQRFH2 in the WebSphere MQ message.

### Exchanging messages between JMS programs through service integration and WebSphere MQ

Usually, you do not have to be aware of conversion between message formats to exchange JMS messages between service integration and WebSphere MQ, because service integration performs the appropriate conversion automatically, including character and numeric encoding. However, you might have to learn about message conversion if your JMS applications do not behave as expected, or if your service integration configuration includes JMS programs or mediations that process messages to or from non-JMS WebSphere MQ programs.

If your service integration applications exchange MapMessage objects with WebSphere MQ applications, you might have to specify a non-default map message encoding format.

### WebSphere MQ message properties: the MQMD and the MQRFH2

WebSphere MQ messages contain message properties in the message descriptor (MQMD) and in the rules and formatting header 2 (MQRFH2). The WebSphere MQ message always includes an MQMD, but the MQRFH2 is optional because some WebSphere MQ applications cannot process messages that contain an MQRFH2. To simplify interoperation, you can configure service integration to omit the MQRFH2 from messages for applications that cannot process the MQRFH2. When service integration omits the MQRFH2, it discards the corresponding service integration header fields and properties.

**Note:** A small amount of the MQRFH2 information is also stored in MQMD fields. However, these MQMD fields are not exact equivalents, tend to be less specific, and cannot be relied upon to provide an adequate substitute for the MQRFH2 information. Therefore if the receiving application can accept an MQRFH2 header, you should always provide one.

Similarly, service integration might receive messages from WebSphere MQ applications that generate messages with no MQRFH2. When service integration receives a message with no MQRFH2, it creates a “best guess” service integration header, by getting as much information as it can from the MQMD, and using default values for the other fields.

For detailed information about the contents of the message descriptor and the message headers, see the WebSphere MQ Application Programming Reference. For details of WebSphere MQ JMS support,

including details of how WebSphere MQ stores JMS message properties and header fields in the MQMD and the MQRFH2, see WebSphere MQ Using Java.

## WebSphere MQ message properties: JMS header fields

The following table shows how service integration maps JMS header fields to and from MQMD and MQRFH2 fields when converting messages to and from WebSphere MQ format.

The table shows the MQRFH2 field as *folder.field*, where *folder* is the name of the MQRFH2 folder that contains the field, and *field* is the name of the field within the MQRFH2 folder.

For several JMS header fields, there is both an MQMD field and an MQRFH2 field. When service integration is converting messages to WebSphere MQ format, it sets both the MQMD and the MQRFH2 fields. When service integration is converting messages from WebSphere MQ format, it sets the JMS header field from the MQRFH2 field if it is available, otherwise from the MQMD field.

*Table 121. JMS, MQMD and MQRFH2 header fields. The first column of this table lists the JMS header fields, and the second column shows the MQMD fields that relate to the JMS header fields in the first column. The third column shows the MQRFH2 fields that relate to the JMS header fields in the first column. The fourth column provides links, where required, to the footnotes that appear after the table.*

| JMS header field | MQMD field | MQRFH2 field | Notes |
|---|---|---|---|
| **JMSCorrelationID** | **CorrelId** | **jms.Cid** | See Note 1. |
| **JMSDeliveryMode** | **Persistence** | **jms.Dlv** | See Note 15. |
| **JMSDestination** | | **jms.Dst** | See Note 16. |
| **JMSExpiration** | **Expiry** | **jms.Exp** | |
| **JMSMessageID** | **MsgId** | | |
| **JMSPriority** | **Priority** | | See Note 2. |
| **JMSRedelivered** | **BackoutCount** | | See Note 3. |
| **JMSReplyTo** | **ReplyToQ** and **ReplyToQMgr** | **jms.Rto** | See Note 16. |
| **JMSTimestamp** | **PutDate** and **PutTime** | **jms.Tms** | |
| **JMSType** | | **mcd.Type** | |

**Note 1:** The MQMD **CorrelId** field can hold a standard WebSphere MQ Correlation ID of 48 hexadecimal digits (24 bytes). The **JMSCorrelationID** can be a `byte[]` value, a string value containing hexadecimal characters and prefixed with “ID:”, or an arbitrary string value not beginning “ID:”. The first two of these represent a standard WebSphere MQ Correlation ID and map directly to or from the MQMD **CorrelId** field (truncated or padded with zeros as applicable); they do not use the MQRFH2 **jms.Cid** field. The third (arbitrary string) uses the MQRFH2 **jms.Cid** field; the first 24 bytes of the string, in UTF-8 format, are written into the MQMD **CorrelID**.

**Note 2:** WebSphere MQ stores the **JMSPriority** value in the MQRFH2 **jms.Pri** field but does not use any value already in that field. Service integration does not check or set the MQRFH2 **jms.Pri** field.

**Note 3:** Service integration sets the **JMSRedelivered** indicator for a message it receives from WebSphere MQ based on the **BackoutCount** field of the MQMD; a non-zero **BackoutCount** value indicates that a previous receive for the message was rolled back.

## WebSphere MQ message properties: JMS defined properties

The following table shows how service integration maps JMS defined properties to and from MQMD and MQRFH2 fields when converting messages to and from WebSphere MQ format.

The table shows the MQRFH2 field as *folder.field*, where *folder* is the name of the MQRFH2 folder that contains the field, and *field* is the name of the field within the MQRFH2 folder.

For several JMS-defined properties, there is both an MQMD field and an MQRFH2 field. When service integration is converting messages to WebSphere MQ format, it sets both the MQMD and the MQRFH2 fields. When service integration is converting messages from WebSphere MQ format, it sets the JMS defined property from the MQRFH2 field if it is available, otherwise from the MQMD field.

*Table 122. JMS properties with MQMD and MQRFH2 fields. The first column of this table lists the JMS defined properties, and the second column shows the MQMD fields that relate to the JMS defined properties in the first column. The third column shows the MQRFH2 fields that relate to the JMS defined properties in the first column. The fourth column provides links, where required, to the footnotes that appear after the table.*

| JMS defined property | MQMD field | MQRFH2 field | Notes |
|---|---|---|---|
| **JMSXAppID** | **PutApplName** | | |
| **JMSXDeliveryCount** | **BackoutCount** | | |
| **JMSXGroupID** | **GroupId** | **jms.Gid** | See Notes 4 and 5. |
| **JMSXGroupSeq** | **MsgSeqNumber** | **jms.Seq** | |
| **JMSXUserID** | **UserIdentifier** | | |

**Note 4:** The MQMD **GroupId** field can hold a standard WebSphere MQ **GroupId** of 48 hexadecimal digits (24 bytes). The **JMSXGroupID** is a string value containing hexadecimal characters and prefixed with "ID:" or an arbitrary string value not beginning "ID:". The first of these represents a standard WebSphere MQ **GroupId** and maps directly to or from the MQMD **GroupId** field (truncated or padded with zeros as applicable). The second (arbitrary string) uses the MQRFH2 **jms.Gid** field; the first 24 bytes of the string, in UTF-8 format, are written into the MQMD **GroupId**.

**Note 5:** When service integration is converting messages to WebSphere MQ format, if the **JMSXGroupID** has been set then service integration also sets the **MQMF_MSG_IN_GROUP** flag in the **MsgFlags** field of the MQMD. Note that when sending group messages, the sending JMS application must ensure that the **MQMF_LAST_MSG_IN_GROUP** flag is set as required (see "WebSphere MQ message properties: JMS provider-specific properties").

## WebSphere MQ message properties: JMS provider-specific properties

The following table shows how service integration maps JMS provider-specific properties to and from MQMD and MQRFH2 fields when converting messages to and from WebSphere MQ format. Typically you use these properties to satisfy special requirements in the receiving application, so you should consult the developer or administrator of the receiving application for details of the required property values.

*Table 123. JSM provider-specific properties with MQMD and MQRFH2 fields. The first column of this table lists the JMS provider-specific properties, and the second column shows the MQMD fields that relate to the JMS provider-specific properties in the first column. The third column shows the MQRFH2 fields that relate to the JMS provider-specific properties in the first column. The fourth column provides links, where required, to the footnotes that appear after the table.*

| JMS provider-specific property | MQMD field | MQRFH2 field | Notes |
|---|---|---|---|
| **JMS_IBM_ArmCorrelator** | | **mqext.Arm** | See Note 6. |
| **JMS_IBM_Character_Set** | **CodedCharacterSetId** | **CodedCharacterSetId** | See Note 7. |
| **JMS_IBM_Encoding** | **Encoding** | **Encoding** | See Note 7. |
| **JMS_IBM_Feedback** | **Feedback** | | |
| **JMS_IBM_Format** | **Format** | **Format** | See Note 7. |
| **JMS_IBM_Last_Msg_In_Group** | **MQMF_LAST_MSG_IN_GROUP** | | See Note 8. |
| **JMS_IBM_MQMD_CorrelId** | **CorrelId** | | See Notes 9 and 10. |

*Table 123. JSM provider-specific properties with MQMD and MQRFH2 fields (continued). The first column of this table lists the JMS provider-specific properties, and the second column shows the MQMD fields that relate to the JMS provider-specific properties in the first column. The third column shows the MQRFH2 fields that relate to the JMS provider-specific properties in the first column. The fourth column provides links, where required, to the footnotes that appear after the table.*

| JMS provider-specific property | MQMD field | MQRFH2 field | Notes |
|---|---|---|---|
| **JMS_IBM_MQMD_MsgId** | **MsgId** | | See Notes 9 and 11. |
| **JMS_IBM_MQMD_Persistence** | **Persistence** | | See Notes 9, 12, and 15. |
| **JMS_IBM_MQMD_ReplyToQ** | **ReplyToQ** | | See Notes 9, 13, and 16. |
| **JMS_IBM_MQMD_ReplyToQMgr** | **ReplyToQMgr** | | See Notes 9, 13, and 16. |
| **JMS_IBM_MsgType** | **MsgType** | | |
| **JMS_IBM_PutDate** | **PutDate** | | |
| **JMS_IBM_PutTime** | **PutTime** | | |
| **JMS_IBM_Report_*** | **Report** | | See Note 14. |
| **JMS_IBM_RMCorrelator** | | **mqext.Wrm** | |
| **JMS_TOG_ARM_Correlator** | | **mqext.Arm** | See Note 6. |

**Note 6:** You should use the name **JMS_TOG_ARM_Correlator** for the ARM correlator. The name **JMS_IBM_ArmCorrelator** is available for compatibility with some existing JMS programs.

**Note 7:** The **JMS_IBM_Character_Set**, **JMS_IBM_Encoding**, and **JMS_IBM_Format** properties contain information about the WebSphere MQ message payload; that is, the part of the WebSphere MQ message that follows the MQRFH2 (if there is one) or the whole WebSphere MQ message, excluding the MQMD, if there is no MQRFH2. For more information about these properties and how to use them, see “Mapping the message body to and from WebSphere MQ format” on page 886.

**Note 8:** **MQMF_LAST_MSG_IN_GROUP** is one of the flags in the **MsgFlags** field of the MQMD.

**Note 9:** The **JMS_IBM_MQMD_CorrelId**, **JMS_IBM_MQMD_MsgId**, **JMS_IBM_MQMD_Persistence**, **JMS_IBM_MQMD_ReplyToQ**, and **JMS_IBM_MQMD_ReplyToQMgr** properties allow JMS applications to override the service integration default processing of WebSphere MQ MQMD fields. When service integration converts messages to WebSphere MQ format, service integration sets the corresponding MQMD field for each of these properties if, and only if, that property has been explicitly set by the application (using `setObjectProperty()` or `setNonNullProperty()`).

Service integration sets each of these properties from the corresponding MQMD field when it converts a message from WebSphere MQ format.

**Note 10:** The **JMS_IBM_MQMD_CorrelId** property overrides the default processing of the **JMSCorrelationID** property. When service integration converts messages to WebSphere MQ format, service integration sets the MQMD **CorrelId** field to the value (`byte[]`) if explicitly set of the **JMS_IBM_MQMD_CorrelId** property, regardless of the value (if any) of the **JMSCorrelationID** property. Setting the **JMS_IBM_MQMD_CorrelId** property does not affect the value of the MQRFH2 **jms.Cid** field.

When service integration converts messages from WebSphere MQ format, service integration sets the **JMS_IBM_MQMD_CorrelId** property to the value (`byte[]`) of the **MQMD CorrelId** field, regardless of the value (if any) of the MQRFH2 **jms.Cid** field.

**Note 11:** The **JMS_IBM_MQMD_MsgId** property overrides the JMS default processing of the **JMSMessageID** property. When service integration converts messages to WebSphere MQ format, service integration checks whether the **JMS_IBM_MQMD_MsgId** property has been

explicitly set. If so, service integration sets the MQMD **MsgId** field to this value (byte[]) , and replaces the unique value of the **JMSMessageID** that JMS allocates to the message.

When service integration converts messages from WebSphere MQ format, service integration sets the **JMS_IBM_MQMD_MsgId** property to the value (`byte[]`) of the MQMD **MsgId** field.

**Note 12:** The **JMS_IBM_MQMD_Persistence** property overrides the default processing of the **JMSDeliveryMode** property. When service integration converts messages to WebSphere MQ format, service integration sets the MQMD **Persistence** field to the value (integer) if explicitly set of the **JMS_IBM_MQMD_Persistence** property, regardless of the value (if any) of the **JMSDeliveryMode** property. Setting the **JMS_IBM_MQMD_Persistence** property does not affect the value of the MQRFH2 **jms.Dlv** field.

When service integration converts messages from WebSphere MQ format, service integration sets the **JMS_IBM_MQMD_Persistence** property to the value (integer) of the MQMD **Persistence** field, regardless of the value (if any) of the MQRFH2 **jms.Dlv** field.

**Note 13:** The **JMS_IBM_MQMD_ReplyToQ** and **JMS_IBM_MQMD_ReplyToQMgr** properties override the default processing of the **JMSReplyTo** property. When service integration converts messages to WebSphere MQ format, service integration sets the MQMD **ReplyToQ** field to the value (string) if explicitly set of the **JMS_IBM_MQMD_ReplyToQ** property and the MQMD **ReplyToQMgr** field to the value (string) if explicitly set of the **JMS_IBM_MQMD_ReplyToQMgr** property, regardless of the value (if any) of the **JMSReplyTo** property. Setting the **JMS_IBM_MQMD_ReplyToQ** or **JMS_IBM_MQMD_ReplyToQMgr** field does not affect the value of the MQRFH2 **jms.Rto** field.

When service integration converts messages from WebSphere MQ format, service integration sets the **JMS_IBM_MQMD_ReplyToQ** and **JMS_IBM_MQMD_ReplyToQMgr** property to the values (string) of the MQMD **ReplyToQ** and **ReplyToQMgr** fields, regardless of the value (if any) of the MQRFH2 **jms.Rto** field.

**Note 14:** For a list of the **JMS_IBM_Report_*** properties, see “Mapping MQMD Report fields to JMS provider-specific properties” on page 897.

**Note 15:** For more information see “Mapping the JMS delivery option and message reliability to and from the WebSphere MQ persistence value.”

**Note 16:** For more information see “Mapping destinations to and from WebSphere MQ queues, topics, and destinations” on page 894.

## Mapping the JMS delivery option and message reliability to and from the WebSphere MQ persistence value

When converting messages between WebSphere MQ format and service integration format, service integration processes the message header fields and properties relating to message delivery mode, reliability, and persistence.

### Quality of service indications in the WebSphere MQ format message

The WebSphere MQ format message contains the following indications of the quality of service:

**MQMD persistence**

This property is present in all WebSphere MQ format messages. The property specifies the quality of service that WebSphere MQ provides for the message as follows:

| MQMD persistence | Quality of service |
| --- | --- |
| MQPER_PERSISTENT | Persistent quality of service. WebSphere MQ assures once and once only delivery of the message. |
| MQPER_NOT_PERSISTENT | Nonpersistent quality of service. WebSphere MQ can discard the message in exceptional circumstances. |
| MQPER_PERSISTENCE_AS_Q_DEF | WebSphere MQ sets the quality of service (persistent or nonpersistent) to the value configured for the destination queue. |

For more information about the WebSphere MQ persistent and nonpersistent qualities of service, see the WebSphere MQ documentation .

**MQRFH2 jms.Dlv (JMSDeliveryMode)**

This property is present in WebSphere MQ format JMS messages that include the MQRFH2 header. The property contains the **JMSDeliveryMode** that was set when the application issued `send` for the message.

## Quality of service indications when service integration converts a message to WebSphere MQ format

Message reliability levels - JMS delivery mode and service integration quality of service describes how service integration sets the message reliability. Briefly: JMS applications send messages with a JMS delivery mode (persistent or nonpersistent), then service integration uses JMS connection factory settings to map the JMS delivery mode to a service integration message reliability setting, and finally additional settings on bus destinations (including foreign destinations and alias destinations) can override this message reliability. When service integration converts the message to WebSphere MQ format, it sets the **MQMD persistence** indicator as follows:

| Service integration message reliability | MQMD persistence |
| --- | --- |
| Reliable persistent | Persistent |
| Assured persistent | Persistent |
| Reliable nonpersistent | Nonpersistent |
| Express nonpersistent | Nonpersistent |
| Best effort nonpersistent | Nonpersistent |

The sending application can optionally override this by setting the **JMS_IBM_MQMD_Persistence** message property in the message.

## Quality of service indications when service integration converts a message from WebSphere MQ format

When service integration receives a message from WebSphere MQ, it uses the **MQMD persistence** value of the message together with the corresponding service integration reliability value that you configure in the WebSphere MQ link receiver or the WebSphere MQ server queue point to determine the reliability of the service integration message.

# Mapping destinations to and from WebSphere MQ queues, topics, and destinations

Service integration messages and WebSphere MQ messages both contain header fields and properties. Some of these header fields and properties contain destinations or destination properties that provide information about send-to and reply-to destinations, and about destinations in the bus forward and reverse routing paths. Because service integration and WebSphere MQ have different definitions for destinations, mappings are used to process the destinations and destination properties when messages are converted between service integration format and WebSphere MQ format.

## Destinations and destination properties in the WebSphere MQ format message

The WebSphere MQ format message contains the following information related to destinations:

**MQXQH RemoteQName**
**MQXQH RemoteQMgrName**

These fields are present in the MQXQH (the WebSphere MQ Transmission-queue header). The MQXQH is attached to messages only while they travel between WebSphere MQ queue managers, or between WebSphere MQ queue managers and service integration buses across a WebSphere MQ link. Sending and receiving applications cannot access these fields.

The **RemoteQName** field contains the name of the send-to queue (WebSphere MQ) or send-to destination (service integration). The **RemoteQMgrName** field identifies the queue manager or queue-sharing group (WebSphere MQ) or service integration bus (service integration) where the send-to queue or destination is located. Usually, the **RemoteQMgrName** field contains the name of the remote queue manager, queue-sharing group, or service integration bus, but it can contain a WebSphere MQ queue manager alias or a service integration virtual queue manager name. Note that these fields are not used for topics.

The **RemoteQName** and **RemoteQMgrName** values can be up to a maximum length of 48 characters, and must conform to WebSphere MQ naming restrictions.

**MQRFH2 jms.Dst (JMSDestination)**

This field is present in WebSphere MQ format JMS messages that include the MQRFH2 header.

The **jms.Dst** field contains a serialized representation (a WebSphere MQ URI) of the send-to JMS destination that was set when the application issued send for the message. Refer to the WebSphere MQ library for more information about the WebSphere MQ URI format for JMS destinations.

When service integration sends a message that has a forward-routing path to WebSphere MQ, it adds an **ibmRoutingPath** attribute to this URI. The **ibmRoutingPath** value identifies the forward routing path from the service integration message. WebSphere MQ does not use the forward routing path, but the send-to destination might be in a remote service integration bus that can use the forward routing path.

**MQMD ReplyToQ**
**MQMD ReplyToQMgr**

These fields are present in all WebSphere MQ format messages.

If the sending application specifies a reply-to queue, the **ReplyToQ** field contains the name of the reply-to queue (WebSphere MQ) or reply-to destination (service integration), and the **ReplyToQMgr** field identifies the queue manager or queue-sharing group (WebSphere MQ) or service integration bus (service integration) where that queue is located. Usually, the **ReplyToQMgr** field contains the name of the queue manager, queue-sharing group, or service integration bus, but it can contain a WebSphere MQ queue manager alias or a service integration virtual queue manager name. If the sending application specifies a reply-to topic, or if it does not specify a reply-to destination, these fields contain null values.

The **ReplyToQ** and **ReplyToQMgr** values can be up to a maximum length of 48 characters, and must conform to WebSphere MQ naming restrictions.

**MQRFH2 jms.Rto (JMSReplyTo)**

This field is present in WebSphere MQ format JMS messages that include the MQRFH2 header and that specify a reply-to destination. WebSphere MQ JMS applications usually use this message attribute as the destination for reply messages, but other (non-JMS) WebSphere MQ applications usually do not use it; they use the MQMD reply-to fields instead.

The **jms.Rto** field contains a serialized representation (a WebSphere MQ URI) of the reply-to JMS destination that is set by the sending JMS application. Refer to the WebSphere MQ library for more information about the WebSphere MQ URI format for JMS destinations.

When service integration sends a message that has a reverse-routing path to WebSphere MQ, service integration adds an **ibmRoutingPath** attribute to this URI. The **ibmRoutingPath** value identifies the reverse-routing path from the service integration message. When the receiving JMS application sends a reply, WebSphere MQ includes the routing path information from the reply-to URI in the send-to URI of the reply message so that service integration can use it for routing the reply message.

**Note:**

- When the sending application specifies a reply-to queue for a message, that queue is usually located in the bus, queue manager, or queue-sharing group to which the sending application connects. This allows the sending application to receive the reply message from the reply-to queue. Service integration applications that send messages to or through WebSphere MQ should not specify a reply-to queue in a different bus, queue manager, or queue-sharing group.
- It is important to understand that it is the receiving application which uses the reply-to destination in a message. The bus, queue manager, or queue-sharing group to which the receiving application connects must be configured with the information that allows routing to the reply-to destination.

## Destination conversion when service integration converts a message to WebSphere MQ format

When service integration converts a message to WebSphere MQ format, it puts the following destination information into the WebSphere MQ format message:

**MQXQH RemoteQName**
**MQXQH RemoteQMgrName**

These fields apply only when service integration is sending the message across a WebSphere MQ link, and only when the destination is a queue.

Service integration sets these fields based on the resolved send-to destination for the message; that is, if the send-to destination is an alias, service integration uses the target bus and target identifier. Processing is then as follows:

- If the send-to destination is in an indirectly-connected bus, it stores the destination name (identifier) as the **RemoteQName** and the bus name as the **RemoteQMgrName**.
- If the send-to destination is in the directly-connected bus and the destination name (identifier) is in the form *queue@queueManager*, it stores the queue name (*queue*) as the **RemoteQName** and the queue manager name (*queueManager*) as the **RemoteQMgrName**.
- If the send-to destination is in the directly-connected bus and the destination name (identifier) is not in the form *queue@queueManager*, it stores the destination name as the **RemoteQName** and the bus name as the **RemoteQMgrName**.

If the send-to destination is in an indirectly-attached service integration bus and its destination name does not comply with WebSphere MQ naming restrictions, you must define an alias destination with a compliant name; the sending application must use the compliant (alias) name. In this case, you must define the alias destination in the remote (indirectly-attached) bus, not the local bus.

If the send-to destination is in an indirectly-attached service integration bus and its bus name does not comply with WebSphere MQ naming restrictions, there must be a virtual queue manager name for the indirectly-attached bus. In this case, the local bus must define the indirectly-attached bus with its virtual queue manager name, not its bus name.

For more information about mapping service integration bus names that do not comply with WebSphere MQ naming restrictions, see How to address bus destinations and WebSphere MQ queues.

**MQRFH2 jms.Dst (JMSDestination)**

If the WebSphere MQ format message includes the MQRFH2 header, service integration serializes the **JMSDestination** header field into a WebSphere MQ URI and stores it in the **JMSDestination** field in the WebSphere MQ message. If the message has a forward-routing path, service integration includes that in the URI as the **ibmRoutingPath** attribute.

**MQMD ReplyToQ**
**MQMD ReplyToQMgr**

The sending JMS application can set these fields directly by using the provider-specific JMS message properties **JMS_IBM_MQMD_ReplyToQ** and **JMS_IBM_MQMD_ReplyToQMgr**. If the sending application does not do this, service integration sets the properties if (and only if) the message has a reply-to destination and that destination is a queue.

Service integration sets these fields based on the unresolved reply-to destination for the message; that is, if the reply-to destination is an alias, service integration uses the alias bus and identifier, not the target bus and identifier. Service integration applications should not provide reply-to destinations that are foreign destinations or have names that include the @ character. Provided applications do not do this, processing is as follows:

- The reply-to destination name (identifier) is stored in the **ReplyToQ** field and the reply-to destination bus name (that is, the local bus name) in the **ReplyToQMgr** field.
- If the virtual queue manager name is different from the local bus name, the virtual queue manager name is stored in the **ReplyToQMgr** field instead of the local bus name.

If the real name of the reply-to destination does not comply with WebSphere MQ naming restrictions (including if the name includes the @ character), you must define an alias destination with a compliant name and the sending application must use the compliant (alias) name. In this case, you must define the alias destination in the local bus, not in the remote (indirectly-attached) bus.

**MQRFH2 jms.Rto (JMSReplyTo)**

If the message has a reply-to destination and the WebSphere MQ format message includes the MQRFH2 header, service integration constructs a WebSphere MQ URI to represent that reply-to destination, and stores the URI in the **JMSReplyTo** property in the WebSphere MQ message. If the reply-to destination is a queue, the URI includes the reply-to destination bus name (the local bus) or the virtual queue manager name (if that is different). If the message has a reverse-routing path, service integration includes that path in the URI in the **ibmRoutingPath** attribute.

## Destination conversion when service integration converts a message from WebSphere MQ format

When service integration converts a message from WebSphere MQ format, it uses the following destination information from the WebSphere MQ format message:

**MQXQH RemoteQName**
**MQXQH RemoteQMgrName**

These fields are applicable only when service integration is receiving the message across a WebSphere MQ link, and only when the destination is a queue.

Service integration interprets the **RemoteQName** field as the destination identifier (always a queue) for the message, and the **RemoteQMgrName** field as the name of the destination bus for the message. If the **RemoteQMgrName** field contains the virtual queue manager name of the local bus, service integration interprets it as the name of the local bus. Service integration then uses the resulting bus and destination identifier combination (which can be an alias destination in the local bus) to deliver the message in the usual way. For the case where the destination bus is a foreign bus, this includes forwarding the message to that foreign bus.

**MQRFH2 jms.Dst (JMSDestination)**

If this field is available, service integration uses it to create the **JMSDestination** header field for the message. If the URI includes the **ibmRoutingPath** attribute, service integration uses that to create the forward-routing path for the message.

If this property is not available (for example, if the WebSphere MQ message has no MQRFH2 header), service integration can create a **JMSDestination** header field from the service integration destination where the message is delivered.

**MQMD ReplyToQ**
**MQMD ReplyToQMgr**

If these fields contain non-null values, service integration uses them to construct the first element of the reverse-routing path for the service integration message, as follows:

- If **ReplyToQMgr** is the local bus name or virtual queue manager name, service integration sets the bus to the local bus and the destination name (identifier) to **ReplyToQ**.
- If **ReplyToQMgr** is a foreign bus defined in the local bus, service integration sets the bus to **ReplyToQMgr** and the destination name (identifier) to **ReplyToQ**.
- If **ReplyToQMgr** is not the local bus name, virtual queue manager name, or a foreign bus defined in the local bus, service integration sets the bus to the directly-attached WebSphere MQ bus and the destination name (identifier) to *queue@queueManager* where *queue* is **ReplyToQ** and *queueManager* is **ReplyToQMgr**.

**MQRFH2 jms.Rto (JMSReplyTo)**

If this field is available, service integration uses it with the MQMD **ReplyToQ** and **ReplyToQMgr** fields to construct the reverse-routing path and **JMSReplyTo** header field for the service integration message. It constructs the reverse-routing path from the first element (which it constructs from the MQMD **ReplyToQ** and **ReplyToQMgr** fields) and any remaining elements that it obtains from the **ibmRoutingPath** attribute (if there is one) of the **JMSReplyTo** URI in the WebSphere MQ message. It constructs the **JMSReplyTo** header field from the first element of the reverse-routing path together with the destination attributes of the **JMSReplyTo** URI in the WebSphere MQ message.

## Mapping MQMD Report fields to JMS provider-specific properties

JMS applications can use report messages as a form of managed request/response processing, to give remote feedback to producers on the outcome of their send operations and the fate of their messages. A JMS application can request different types of report message by setting JMS_IBM_Report_Xxxx message properties and options.

JMS applications can request the following types of report message by setting the appropriate JMS_IBM_Report_Xxxx message properties and options. The options have the same general syntax and meaning:

**MQRO**_*report-type*
A report message of the indicated type is generated that contains the WebSphere MQ message descriptor (MQMD) of the original message. It does not contain any message body data.

**MQRO**_*report-type*_**WITH_DATA**
A report message of the indicated type is generated that contains the MQMD, any MQ headers, and 100 bytes of body data.

**MQRO**_*report-type*_**WITH_FULL_DATA**
A report message of the indicated type is generated that contains all data from the original message.

Use the following prefix with each option: com.ibm.websphere.sib.api.jms.

For example, to request a Confirm on delivery (COD) report message with full data, the JMS application must set JMS_IBM_Report_COD to the value com.ibm.websphere.sib.api.jms.MQRO_COD_WITH_FULL_DATA.

For each type of report message, the following table shows the JMS_IBM_Report_Xxxx message property that a JMS application can set, and the MQMD Report field options that map to the property.

| Type of report message | Description | JMS_IBM_Report_Xxxx message property and options |
|---|---|---|
| Exception | Send a report message if the request message cannot be put to the target queue. The exception report messages are generated when a message has been rerouted to an exception destination. | JMS_IBM_Report_Exception<br>• MQRO_EXCEPTION<br>• MQRO_EXCEPTION_WITH_DATA<br>• MQRO_EXCEPTION_WITH_FULL_DATA |
| Discard | Discard the original request message rather than sending it to an exception destination. You can use this option with the JMS_IBM_Report_Exception property set to MQRO_EXCEPTION_WITH_FULL_DATA to return an undeliverable request message to its sender. | JMS_IBM_Report_Discard_Msg<br>• TRUE<br>• FALSE |
| Expiration | Send a report message if the request message passes its expiry time. | JMS_IBM_Report_Expiration<br>• MQRO_EXPIRATION<br>• MQRO_EXPIRATION_WITH_DATA<br>• MQRO_EXPIRATION_WITH_FULL_DATA |
| Confirm on arrival (COA) | Send a report message when the request message has been put to the target queue.<br><br>For publish/subscribe messaging, the COA report message is generated only on the producers messaging engine. Therefore, such reports are relevant only to local subscriptions.<br><br>For point-to-point messaging, COA messages are generated when the message arrives at the final destination. For partitioned queues, the report message is generated only when the put operation has committed and a final destination has therefore been selected. Any With_Data or With_Full_Data report options specified are ignored; the COA report message deals only with message headers.<br><br>If a forward-routing path is used, the COA message are generated when the message arrives at the final destination in the path. | JMS_IBM_Report_COA<br>• MQRO_COA<br>• MQRO_COA_WITH_DATA<br>• MQRO_COA_WITH_FULL_DATA |

| Type of report message | Description | JMS_IBM_Report_Xxxx message property and options |
|---|---|---|
| Confirm on delivery (COD) | Send a report message when the request message has been removed from the queue or topic space by a message consumer.<br><br>For publish/subscribe messaging, the COD message is generated when all subscribers have received the request message. Therefore, there is one COD message generated for every COA. When a message is consumed by a subscriber, the reference count of the message on the topic space is reduced. When the reference count reaches zero, the message is removed from the topic space then a COD report message is generated.<br><br>For point-to-point messaging, the COD message is generated after the message has been successfully received by a consuming application. Any With_Data or With_Full_Data report options specified are ignored; the COD report message deals only with message headers. | JMS_IBM_Report_COD<br>• MQRO_COD<br>• MQRO_COD_WITH_DATA<br>• MQRO_COD_WITH_FULL_DATA |
| Positive action notification (PAN) | Ask the consumer application to send a report message when it has successfully processed the request message. | JMS_IBM_Report_PAN<br>• TRUE<br>• FALSE |
| Negative action notification (NAN) | Ask the consumer application to send a report message if it has not successfully processed the request message. | JMS_IBM_Report_NAN<br>• TRUE<br>• FALSE |

The requesting application can control other aspects of the report message as follows:

- How the message Id is generated for the report message and any reply message:

  **MQRO_New_Msg_Id**
  This the default. A new message Id is generated for the report message.

  **MQRO_Pass_Msg_Id**
  The message Id of the report message is set to the message Id of the request message.

- How the correlation Id of the report or reply message is to be set.

  **MQRO_Copy_Msg_Id_To_Correl_Id**
  This the default. the correlation Id of the report message is set to the message Id of the request message.

  **MQRO_Pass_Correl_Id**
  The correlation Id of the report message is set to the correlation Id of the request message.

For more information about report messages and the associated properties and options refer to the *Using Java* section of the WebSphere MQ information center, available from the WebSphere MQ library.

# Mapping additional MQRFH2 header fields in service integration

In the WebSphere MQ message header (MQRFH2), there are additional fields that are specific to the service integration bus and that allow for functions that are not used in WebSphere MQ. When WebSphere MQ transports a message from one service integration bus to another service integration bus, these fields convey information that can be used by service integration applications but is not required by WebSphere MQ.

The additional fields are inserted in the MQRFH2 header of application messages, in the <sib> and <jms> folders. These fields do not appear as JMS message fields or properties.

When a message is sent to WebSphere MQ, a <sib> folder is included in the MQRFH2 header of the message if both of the following are true:

- The WebSphere MQ queue point attributes of the service integration destination are configured to use MQRFH2 headers.
- The fields that correspond to the <sib> folder content are set in the service integration message.

| MQRFH2 header and field (<jms> folder) | SIBusMessage field or property |
|---|---|
| Frp (appended to Dst field) | Forward routing path header field |
| Rrp (appended to Rto field) | Reverse routing path header field |

| MQRFH2 header and field (<sib> folder) | SIBusMessage field or property |
|---|---|
| RTopic | Reply topic |
| RPri | Reply priority |
| RPer | Reply persistence |
| RTTL | Reply time to live |
| JsApiUserId | Application user ID (JMSXUserId) for the service integration application |
| JsDst | JMS destination |
| JsFmt | Message format |
| JsSysMsgId | System message identifier |

## Mapping the JMS Destination property between service integration and WebSphere MQ

The properties of service integration destinations differ from those used by WebSphere MQ queues, and they cannot be mapped exactly. When service integration uses WebSphere MQ to transport a message, it is useful to keep both representations of the JMS destination property in the message. To address this, when a message leaves service integration and enters WebSphere MQ, an additional **RFH2** property is introduced into the RFH2 header to store the service integration destination property.

The service integration destination property is serialized, formatted as a hexadecimal string, then stored using the **JsDst** property of the service integration RFH2 folder, the <sib> folder. WebSphere MQ applications do not make use of this folder, but if the message is to be retrieved by another service integration application, it can use the information.

For example, a service integration destination SIQ1 is localized on a WebSphere MQ queue MQQ1, residing on queue manager QM1. The following actions occur when a service integration application sends a message to SIQ1:

- A serialized representation of PMQ1 is placed in the <sib> folder of the RFH2 header, using the **JsDst** property.

- The message is stored on `MQQ1`.
- The string "`queue://QM1/MQQ1`" is also placed in the `<jms>` folder of the RFH2 header, using the **Dst** property.

This follows the convention used by the WebSphere MQ messaging provider to encode JMS destinations. If the message is retrieved by a service integration application, the JMS destination can be recovered from the `<sib>` folder of the RFH2 header. If the message is retrieved by a WebSphere MQ application, the JMS destination can be recovered from the contents of the `<jms>` folder of the RFH2 header.

**Note:** If a WebSphere MQ server bus member is configured so that it does not use RFH2 headers, the JMS destination is not preserved when the message enters WebSphere MQ. In this situation, a service integration application can still retrieve the JMS message, but any attempt to examine the JMS destination property causes a JMS exception.

## How to process WebSphere MQ message headers

WebSphere MQ messages can optionally include additional headers, or alternative headers, to the MQRFH2 header, which contains JMS properties. WebSphere Application Server application programs can use the com.ibm.mq.headers classes to access headers in messages from WebSphere MQ and to construct headers in messages to WebSphere MQ.

### WebSphere MQ message headers

WebSphere MQ messages always include a message descriptor (MQMD). They can also include headers that contain additional information about the messages; for example, messages to or from JMS applications usually include an MQRFH2 header that contains message properties. WebSphere MQ defines the format and usage of some headers (for example, MQRFH2) and also allows users and third-party software providers to define their own custom headers.

Typically it is not necessary for application programs to process WebSphere MQ message headers. Most WebSphere MQ applications either do not use headers at all, or only use the MQRFH2 header, and the service integration and WebSphere MQ messaging providers automatically process the MQRFH2 header when you are communicating with these applications. However, if you are communicating with a WebSphere MQ application that uses or creates additional or different headers, then your WebSphere Application Server application can use the com.ibm.mq.headers classes to create the headers in messages it sends, and process them in messages it receives.

In the WebSphere MQ message, the headers (if there are headers) are at the start of the message, before the message payload. Each header contains fields that describe the following header, or the payload if there are no more headers; the MQMD contains the fields that describe the first header, or the payload if there are no headers. The MQMD and the MQRFH2 header do not normally appear in a JMS message. When the messaging provider converts a WebSphere MQ message into a JMS message, it uses information from the MQMD and MQRFH2 header to set JMS header fields and properties. Similarly, when the messaging provider converts a JMS message into a WebSphere MQ message, it uses the JMS header fields and properties to construct the MQMD and MQRFH2 header.

The JMS provider handles other headers in WebSphere MQ messages by converting the WebSphere MQ message to or from a JMS BytesMessage; the headers appear at the start of the message body, followed by the WebSphere MQ message payload (if any). The **JMS_IBM_Format** property of the JMS message indicates the format of the data in the message body (in this case, first header) and the **JMS_IBM_Encoding** and **JMS_IBM_Character_Set** properties indicate its encoding and CCSID.

### Processing WebSphere MQ message headers in a JMS BytesMessage

The com.ibm.mq.headers package contains classes and interfaces that you can use to parse and manipulate WebSphere MQ headers in the body of a JMS BytesMessage. The MQHeader interface

provides general-purpose methods for accessing header fields and for reading and writing message content. Each header type has its own class that implements the MQHeader interface and adds getter and setter methods for individual fields. For example, the MQCIH class represents the MQCIH (CICS Bridge) header type. The header classes perform any necessary data conversion automatically, and can read or write data in any specified numeric encoding or character set (CCSID).

Two helper classes, MQHeaderIterator and MQHeaderList, assist with reading and decoding (parsing) the header content in messages:

- MQHeaderIterator works like a java.util.Iterator. For as long as there are more headers in the message, the `next()` method returns true, and the `nextHeader()` or `next()` method returns the next header object.
- MQHeaderList works like a java.util.List. Like MQHeaderIterator, it parses header content, but it also allows you to search for particular headers, add new headers, remove existing headers, update header fields, and then write the header content back to a message. Alternatively, you can create an empty MQHeaderList, then populate it with header instances and write it to a message once or repeatedly.

Every header class implements the MQHeader interface, which provides the methods `int read (java.io.DataInput message, int encoding, int characterSet)` and `int write (java.io.DataOutput message, int encoding, int characterSet)`. The java.io.DataInputStream and java.io.DataOutputStream classes implement DataInput and DataOutput respectively. You can obtain DataInput and DataOutput objects from byte arrays carried in JMS messages, as in the following example, which processes a single MQCIH header:

```
import java.io.*;
import javax.jms.*;
import com.ibm.mq.headers.*;
...
BytesMessage bytesMessage = (BytesMessage) msg; // Message received from JMS consumer
byte[] bytes = new byte [(int) bytesMessage.getBodyLength ()];
bytesMessage.readBytes (bytes);
DataInput in = new DataInputStream (new ByteArrayInputStream (bytes));
MQCIH cih = new MQCIH (in,
   bytesMessage.getIntProperty("JMS_IBM_Encoding"),
   819);
```

Alternatively, you can use the MQHeaderIterator class to process a sequence of headers, replacing the line starting `MQCIH cih = new MQCIH` with:

```
MQHeaderIterator it = new MQHeaderIterator (in,
   bytesMessage.getStringProperty("JMS_IBM_Format"),
   bytesMessage.getIntProperty("JMS_IBM_Encoding"),
   819);
while (it.hasNext()) {
   MQHeader item = (MQHeader) it.next();
   ...
}
```

This example creates a single header (an MQCIH type header) and adds it into a BytesMessage:

```
import java.io.*;
import javax.jms.*;
import com.ibm.mq.constants.CMQC;
import com.ibm.mq.headers.*;
...
MQCIH header = new MQCIH();
ByteArrayOutputStream out = new ByteArrayOutputStream ();

header.write (new DataOutputStream (out), CMQC.MQENC_NATIVE, 819);
byte[] bytes = out.toByteArray ();
BytesMessage newMsg = origSes.createBytesMessage();
newMsg.writeBytes(bytes);
```

This example uses the MQHeaderList class to add two headers into a BytesMessage:

```
import java.io.*;
import javax.jms.*;
import com.ibm.mq.constants.CMQC;
import com.ibm.mq.headers.*;
...
byte[] outheaders = null;
byte[] outbody = ...
try {
    MQHeaderList it = new MQHeaderList ();
    MQHeader header1 = ... // Could be any header type
    MQHeader header2 = ... // Could be any header type
    ByteArrayOutputStream out = new ByteArrayOutputStream ();
    DataOutput dout = new DataOutputStream(out);
    it.add(header1);
    it.add(header2);
    it.write(dout);
    outheaders = out.toByteArray();
} catch (Exception e) {
    System.out.println("error generating MQ message headers : " + e);
}
BytesMessage newMsg = origSes.createBytesMessage();
newMsg.writeBytes(outheaders);
newMsg.writeBytes(bytes);

newMsg.setStringProperty("JMS_IBM_Format", "MQCICS");
newMsg.setIntProperty("JMS_IBM_Encoding", CMQC.MQENC_NATIVE);
newMsg.setIntProperty("JMS_IBM_Character_Set", 819);
```

Always use the correct values for the encoding and characterSet arguments. When you read headers, specify the encoding and CCSID with which the byte content was originally written. When writing headers, specify the encoding and CCSID that you want to produce. The data conversion is performed automatically by the header classes.

### More information about the com.ibm.mq.headers classes

The com.ibm.mq.headers package is part of the WebSphere MQ Resource Adapter, which is installed automatically in WebSphere Application Server. This package comprises a set of classes and interfaces that allow the Java programmer to work with WebSphere MQ Message Headers. These include the MQHeaderIterator and MQHeaderList classes mentioned in this topic, and classes for some commonly used WebSphere MQ Message Headers, including:

- MQCIH – CICS bridge header
- MQIIH – IMS™ information header
- MQSAPH – SAP header

You can also define classes representing your own headers.

## WebSphere MQ functions not supported by service integration

There are various functions available in a WebSphere MQ network that are not available on a service integration bus.

The following list helps you identify those functions but it is given as guidance rather than a complete definition. Functions not supported include:

1. Native MQ client (this includes client applications that make use of the base MQ classes for Java) attach.
2. Message segmentation.
3. Message grouping.
4. The MQMD Offset. Original length, MsgFlags, MsgSeqNumber, and GroupId fields are not supported because Message grouping and message segmentation are not supported.

5. Distribution lists.
6. Reference messages.
7. Triggering.
8. Alternate user authority.
9. Pass/set identity context.
10. In a program, setting the attributes of a queue (that is, the equivalent function of MQSET).
11. Confirmation of arrival/delivery.
12. Cluster sender/receiver channels (and cluster workload exits), because a messaging engine cannot participate in a WebSphere MQ cluster.
13. Server and requestor channels.
14. API crossing exits.
15. Data conversion exits.
16. Channel exits.
17. The equivalent to the MCAUSER and PUTAUTH fields of a channel.
18. Networks based on NetBIOS, SPX or SNA.
19. Message based command server.
20. PCF (Programmable Canonical Form messages).
21. Model queues. Service integration does not allow you to define model queues of a given name. Service integration technology supports only one model queue called the SYSTEM.DEFAULT.MODEL.QUEUE.
22. Dynamic queue name prefix length. Service integration suffixes all dynamic queue names with "_Q" and a unique id. This restricts the name specified in the dynamic queue name field of the Object Descriptor to up to 12 chars. If this name is greater than 12 characters, then it is truncated to 12 characters. In service integration, it is not possible to create a dynamic queue with the full name specified in the dynamic queue name field of the Object Descriptor.
23. Mark skip backout option.
24. Signal option on a get request.
25. Version 3 get message options structures.
26. All queue properties (the properties of a service integration destination do not map, one for one, to the properties of a WebSphere MQ local queue, for example).
27. Poisoned messages. Service integration bus local destination definitions have a maximum failed deliveries count (that is, the equivalent to the WebSphere MQ BackoutThreshold value) but there is no equivalent of the WebSphere MQ backout requeue queue name. In service integration technology, poisoned messages are instead backed out to an exception destination. Additionally, in service integration technology, when the number of times an application backs out a poisoned message is equal to the maximum failed deliveries count, the message is automatically backed out to an ExceptionDestination. If there is more than one message in the current unit of recovery, only the poisoned message is backed out to the ExceptionDestination. The remainder of the messages in the unit of recovery are backed out to the destination from which they were read.
28. A strict limitation of 48 bytes on the name of a queue. Service integration bus destination names can be greater than 48 bytes in length. If a destination name is to be returned to a WebSphere MQ JMS application, then it is important to use 48 byte destination lengths. Though, in some cases, it might be feasible to define an alias destination with a name length of up to 48 bytes to map to a local destination with a name of length greater than 48 bytes.

# Chapter 18. Programming to use message-driven beans

Applications can use message-driven beans as asynchronous message consumers. You deploy a message-driven bean as a message listener for a destination. When a message arrives at the destination, the EJB container invokes the message-driven bean automatically without an application having to explicitly poll the destination.

### About this task

You can use a tool such as Rational Application Developer to develop applications that use message-driven beans. You can use the WebSphere Application Server runtime tools, such as the administrative console, to deploy and administer applications that use message-driven beans.

For more information about implementing enterprise applications that use message-drive beans, see the following topics:

### Procedure

- Develop message-driven beans.
- Design an enterprise application to use message-driven beans.
- Develop an enterprise application to use message-driven beans.
- Deploy an enterprise application to use message-driven beans with JCA 1.5-compliant resources.
- Deploy an enterprise application to use message-driven beans with listener ports.

## Developing message-driven beans

You can develop a bean implementation class for a message-driven bean as introduced by the Enterprise JavaBeans specification. A message-driven bean (MDB) is a message consumer that implements business logic and runs on the server.

### Before you begin

Determine the messaging model you want for your application regarding use of topics, queues, producers and consumers, publish or subscribe, and so on. You can refer to the message-driven bean component contract that is described in the Enterprise JavaBeans™ specification.

### About this task

A message-driven bean (MDB) is a consumer of messages from a Java Message Service (JMS) provider. An MDB is invoked on arrival of a message at the destination or endpoint that the MDB services. MDB instances are anonymous, and therefore, all instances are equivalent when not actively servicing a client message. The container controls the life cycle of bean instances, which hold no state that is visible to a client.

The following example is a basic message-driven bean:

```
@MessageDriven(activationConfig={
                @ActivationConfigProperty(propertyName="destination",     propertyValue="myDestination"),
                @ActivationConfigProperty(propertyName="destinationType", propertyValue="javax.jms.Queue")
})
public class MsgBean implements javax.jms.MessageListener {

  public void onMessage(javax.jms.Message msg) {

      String receivedMsg = ((TextMessage) msg).getText();
      System.out.println("Received message: " + receivedMsg);
```

© IBM Corporation 2002, 2009

```
   }
}
```

As with other enterprise bean types, you can also declare metadata for message-driven beans in the deployment descriptor rather than using annotations, for example:

```
<?xml version="1.0" encoding="UTF-8"?>

<ejb-jar id="EJBJar_1060639024453" version="3.0"
      xmlns="http://java.sun.com/xml/ns/javaee"
      xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
      xsi:schemaLocation="http://java.sun.com/xml/ns/javaee http://java.sun.com/xml/ns/javaee/ejb-jar_3_0.xsd"
      metadata-complete="false">
  <enterprise-beans>

    <message-driven>

      <ejb-name>MsgBean</ejb-name>
      <ejb-class>com.acme.ejb.MsgBean</ejb-class>
      <activation-config>
         <activation-config-property>
            <activation-config-property-name>destination</activation-config-property-name>
            <activation-config-property-value>myDestination</activation-config-property-value>
         </activation-config-property>
         <activation-config-property>
           <activation-config-property-name>destinationType</activation-config-property-name>
           <activation-config-property-value>javax.jms.Queue</activation-config-property-value>
        </activation-config-property>
      </activation-config>

    </message-driven>

  </enterprise-beans>
</ejb-jar>
```

## Procedure

- Code the business logic of the message-driven bean, which must implement the appropriate message listener interface defined by the messaging type; for example, javax.jms.MessageListener. The business logic is invoked when the message listener method of the MDB is called to service a message; for example, `MessageListener.onMessage()`. If the MDB implements more than one interface, denote the message listener interface by coding the `messageListenerInterface` attribute of the `MessageDriven` annotation, or by coding the `<messaging-type>` element of the `message-driven` deployment descriptor element. You do not have to specify which is the message listener interface, as long as there is only one interface other than `java.io.Serializable`, `java.io.Externalizable`, or any of the `javax.ejb` package interfaces.
- You can optionally define message destination references on any type of enterprise bean. A message destination reference is a logical name by which an enterprise bean can refer to a message destination. The `Resource` annotation is used to inject a message destination reference, for example:

  ```
  @Resource (name="jms/Outlet", type=javax.jms.Queue) Queue salesOutlet;
  ```

  Alternatively, you can use the `<message-destination-ref>` element in the deployment descriptor to specify the message destination reference; for example:

  ```
  <message-destination-ref>
     <message-destination-ref-name>jms/Outlet</message-destination-ref-name>
     <message-destination-type>javax.jms.Queue</message-destination-type>
     <injection-target>
       <injection-target-class>com.acme.ejb.MsgBean</injection-target-class>
       <injection-target-name>salesOutlet</injection-target-name>
    </injection-target>
  </message-destination-ref>
  ```

  The `message-destination-ref` element is similar to the `resource-env-ref` element, but also has subelements, `message-destination-usage` with possible values `Produces`, `Consumes` or

ProducesConsumes, and message-destination-link. You can use the message-destination-link element to tie two or more message-destination-ref references in the deployment descriptor together, which allows the deployer to bind the destination for several enterprise beans all at once, to the same destination. The message-destination-link value must match the message-destination-name value in the message-destination element; for example:

```
<ejb-jar>

  <enterprise-beans>

    <session>
      <ejb-name>OutletBean</display-name>
      ...
      <message-destination-ref>
        <message-destination-ref-name>jms/target</message-destination-ref-name>
        <message-destination-type>javax.jms.Queue</message-destination-type>
        <message-destination-usage>Produces</message-destination-usage>
        <message-destination-link>destination</message-destination-link>
      </message-destination-ref>
      ...
    </session>

    <session>
      <ejb-name>InletBean</display-name>
      ...
      <message-destination-ref>
        <message-destination-ref-name>jms/source</message-destination-ref-name>
        <message-destination-type>javax.jms.Queue</message-destination-type>
        <message-destination-usage>Consumes</message-destination-usage>
        <message-destination-link>destination</message-destination-link>
      </message-destination-ref>
      ...
    </session>

    <message-driven>
      <ejb-name>InletBean</display-name>
      ...

      <ejb-name>MsgBean</ejb-name>
      <ejb-class>com.acme.MsgBean</ejb-class>
      <messaging-type>javax.jms.MessageListener</messaging-type>
      <message-destination-type>javax.jms.Queue</message-destination-type>
      <message-destination-link>destination</message-destination-link>

      ...
    </message-driven>

  </enterprise-beans>
      ...
  <assembly-descriptor>
    ...
    <message-destination>
      <message-destination-name>destination</message-destination-name>
    </message-destination>
    ...
  </assembly-descriptor>

</ejb-jar>
```

The message-destination-link element can refer to a destination that is defined in a different Java archive (JAR) file within the same application, as with an ejb-link element. For example, to link to the destination, ProduceQueue, defined in the grocery.jar file, enter the following line in the deployment descriptor:

```
<message-destination-link>grocery.jar#ProduceQueue</message-destination-link>
```

- As with any enterprise bean, you can package a message-driven bean in a JAR file, or in a web application archive (WAR) file.

## Results

You developed a simple message-driven bean, along with some deployment and packaging options.

## What to do next

Read related information about designing an enterprise application that uses message-driven beans.

# Designing an enterprise application to use message-driven beans

To help you design your enterprise application, consider a generic enterprise application that uses one message-driven bean to retrieve messages from a JMS queue destination, and passes the messages on to another enterprise bean that implements the business logic.

## About this task

To design an enterprise application to use message-driven beans, complete the following steps:

## Procedure

1. Identify the message listener interface for the message type that the message-driven bean is to handle. The message-driven bean class must implement this message listener interface. For example, an EJB message-driven bean class used for JMS messaging must implement the javax.jms.MessageListener interface.
2. Identify the resources that the application is to use. This helps to identify the properties of resources that must be used within the application and configured as application deployment descriptors or within WebSphere Application Server.

*Table 124. JMS resource types and examples of their properties. The left hand column of this table lists the JMS resource types, and the right hand column shows examples of the properties of each of the JMS resource types shown in the left hand column.*

| JMS resource type | Properties (for example) |
|---|---|
| JMS connection factory | **Name:** SamplePtoPQueueConnectionFactory<br>**JNDI Name:** Sample/JMS/QCF |
| JMS destination | **Name:** Q1<br>**JNDI Name:** Sample/JMS/Q1 |
| J2C activation specification properties | **Name:** MyMDBsActivationSpec<br>**JNDI Name:** eis/MyMDBsActivationSpec<br>**Destination JNDI Name:** MyQueue<br>**Destination type:** javax.jms.Queue |
| Message-driven bean (deployment properties) | **Name:** JMSppSampleMDBBean<br>**Transaction type:** Container<br>**Message selector:** JMSType='car'<br>**Acknowledge mode:** Dups OK Acknowledge<br>**Destination type:** javax.jms.Queue<br>**ActivationSpec JNDI name:** MyMDBsActivationSpec |
| Business logic bean | **Name:** MyLogicBean |

   Ensure that you use consistent values where needed; for example, the JNDI name for the J2C activation specification must be the same in both the activation specification and the Message-driven bean deployment attributes.
3. Separate out the business logic. You should develop a message-driven bean to delegate the business processing of incoming messages to another enterprise bean. This provides clear separation of message handling and business processing. This also enables the business processing to be invoked by either the arrival of incoming messages or, for example, from a WebSphere J2EE client.
4. Decide whether to configure security. Messages arriving at a destination being processed by a listener have no client credentials associated with them; the messages are anonymous. Security depends on

the role specified by the RunAs Identity for the message-driven bean as an EJB component. For more information about EJB security, see EJB component security.

5. Understand how best effort nonpersistent messages are handled by the default messaging provider.

   If you have a non-transactional message-driven bean, the system either deletes the message when the message-driven bean starts, or when the message-driven bean completes. If the message-driven bean generates an exception, and therefore does not complete, the system takes one of the following actions:

   - If the system is configured to delete the message when the message-driven bean completes, then the message is despatched to a new instance of the message-driven bean, so the message has another opportunity to be processed.
   - If the system is configured to delete the message when the message-driven bean starts, then the message is lost.

   The message is deleted when the message-driven bean starts if the quality of service is set to Best effort nonpersistent. For all other qualities of service, the message is deleted when the message-driven bean completes.

## Developing an enterprise application to use message-driven beans

Applications can use message-driven beans as asynchronous message consumers. You deploy a message-driven bean as a message listener for a destination. The message-driven bean is invoked by an activation specification or a JMS listener when a message arrives on the input destination that is being monitored.

### About this task

You develop an enterprise application to use a message-driven bean as with any other enterprise bean, except that a message-driven bean does not have a home interface or a remote interface.

You should develop your message-driven bean to delegate the business processing of incoming messages to another enterprise bean, which provides clear separation of message handling and business processing. This separation also means that the business processing can be invoked either by the arrival of incoming messages or, for example, by a WebSphere J2EE client. Responses can be handled by another enterprise bean acting as a sender bean, or they can be handled in the message-driven bean.

EJB 2.0 message-driven beans support only Java Message Service (JMS) messaging. EJB 2.1 and EJB 3 message-driven beans can support other messaging types in addition to JMS. All message-driven beans must implement the MessageDrivenBean interface. For JMS messaging, a message-driven bean must also implement the message listener interface javax.jms.MessageListener. Other Java EE Connector Architecture (JCA)-compliant resource adapters might provide their own message listener interfaces that must be implemented.

You can use the New Enterprise Bean wizard of Rational Application Developer to create an enterprise bean with a bean type of Message-driven bean. The wizard creates appropriate methods for the type of bean.

By convention, the message-driven bean class is named *name*Bean, where *name* is the name you assign to the message-driven bean; for example:

```
public class MyJMSppMDBBean implements MessageDrivenBean, javax.jms.MessageListener
```

A message-driven bean can be registered with the EJB timer service for time-based event notifications if it also implements the javax.ejb.TimedObject interface, and invokes the timer callback method by the following call: `void ejbTimeout(Timer)`. At the scheduled time, the container then calls the message-driven bean ejbTimeout method.

The message-driven bean class must define and implement the following methods:

- onMessage(message), which must meet the following requirements:
  - The method must have a single argument of type javax.jms.Message.
  - The `throws` clause must not define any application exceptions.
  - If the message-driven bean is configured to use bean-managed transactions, it must call the javax.transaction.UserTransaction interface to scope the transactions. Because these calls occur inside the onMessage() method, the transaction scope does not include the initial message receipt. For more information, see the topic about message-driven beans transaction support.

  To handle the message within the onMessage() method (for example, to pass the message on to another enterprise bean), you use standard JMS. This is known as bean-managed messaging.

  If you are using a JCA-compliant resource adapter with a different message listener interface, another method besides the onMessage() method might be needed. For information about the message listener interface needed, see the documentation that was provided with your JCA-compliant resource adapter.
- ejbCreate()

  You must define and implement an ejbCreate method for each way in which you want a new instance of an enterprise bean to be created.
- ejbRemove()

  This method is invoked by the container when a client invokes the remove method inherited by the enterprise bean home interface from the javax.ejb.EJBHome interface. This method must contain any code that you want to execute before an enterprise bean instance is removed from the container (and the associated data is removed from the data source).
- ejbTimeout(Timer)

  This method is needed only to support notifications from the timer service, and contains the business logic that handles time events received.

## Procedure

1. Create the Enterprise Application project.
2. Create the message-driven bean class. You can use the New Enterprise Bean wizard of Rational(r) Application Developer to create the enterprise bean with a bean type of Message-driven bean.

   For an example of how to create the message-driven bean class, see the Example section of this topic. For more information, see *Creating message-driven beans* in the Rational Application Developer information center. The result of this step is a message-driven bean that can be assembled into an EAR file for deployment.
3. Optional: Use the EJB deployment descriptor editor to review and, if needed, change the deployment attributes. You can use the EJB deployment descriptor editor to review deployment attributes that you specified on the EJB creation wizard (such as **Transaction type** and **Message selector**) and other default deployment attributes.

   If needed, you can override the values of these attributes later, after the enterprise application has been exported into an EAR file for deployment, as described in “Configuring deployment attributes for a message-driven bean against JCA 1.5-compliant resources” on page 697 and “Configuring deployment attributes for a message-driven bean against a listener port” on page 700.

   a. In the property pane, select the **Bean** tab.

   b. On the main panel, configure the **Transaction type** attribute.

      **Transaction type**
      This attribute determines whether the message-driven bean manages its own transactions, or whether the container manages transactions on behalf of the bean.
      **Bean** The message-driven bean manages its own transactions.
      **Container**
      The container manages transactions on behalf of the bean.

   c. Under **Activation Configuration**, review the following attributes:

      **acknowledgeMode**
      This attribute determines how the session acknowledges any messages it receives.

**Auto Acknowledge**
The session automatically acknowledges delivery of each message.

**Dups OK Acknowledge**
The session lazily acknowledges the delivery of messages. This setting is likely to result in the delivery of some duplicate messages if JMS fails, so it should be used only by consumer applications that are tolerant of duplicate messages.

As defined in the EJB specification, clients cannot use the Message.acknowledge() method to acknowledge messages. If a value of CLIENT_ACKNOWLEDGE is passed on the create*xxx*Session call, then messages are automatically acknowledged by the application server and the Message.acknowledge() method is not used.

**Note:**

The acknowledgement is sent when the message is deleted.

If you have a non-transactional message-driven bean, the system either deletes the message when the message-driven bean starts, or when the message-driven bean completes. If the message-driven bean generates an exception, and therefore does not complete, the system takes one of the following actions:

- If the system is configured to delete the message when the message-driven bean completes, then the message is despatched to a new instance of the message-driven bean, so the message has another opportunity to be processed.
- If the system is configured to delete the message when the message-driven bean starts, then the message is lost.

The message is deleted when the message-driven bean starts if the quality of service is set to Best effort nonpersistent. For all other qualities of service, the message is deleted when the message-driven bean completes.

**destinationType**
This attribute determines whether the message-driven bean uses a queue or topic destination.

**Queue**
The message-driven bean uses a queue destination.

**Topic** The message-driven bean uses a topic destination.

**subscriptionDurability**
This attribute determines whether a JMS topic subscription is durable or nondurable.

**Durable**
A subscriber registers a durable subscription with a unique identity that is retained by JMS. Subsequent subscriber objects with the same identity resume the subscription in the state it was left in by the earlier subscriber. If there is no active subscriber for a durable subscription, JMS retains the subscription messages until they are received by the subscription or until they expire.

**Nondurable**
Nondurable subscriptions last for the lifetime of their subscriber object. This means that a client sees the messages published on a topic only while its subscriber is active. If the subscriber is not active, the client is missing messages published on its topic.

A nondurable subscriber can only be used in the same transactional context (for example, a global transaction or an unspecified transaction context) that existed when the subscriber was created.

**messageSelector**
This attribute determines the JMS message selector that is used to select which messages the message-driven bean receives. For example:

```
JMSType='car' AND color='blue' AND weight>2500
```

The selector string can refer to fields in the JMS message header and fields in the message properties. Message selectors cannot reference message body values.

d. Specify bindings deployment attributes.

Under **WebSphere Bindings**, select the **JCA Adapter** option then specify the bindings deployment attributes:

**ActivationSpec JNDI name**
This attribute specifies the JNDI name of the activation specification that is used to deploy this message-driven bean. This name must match the name of an activation specification that you define to WebSphere Application Server.

**ActivationSpec Authorization Alias**
This attribute specifies the name of an authentication alias used for authentication of connections to the JCA resource adapter. An authentication alias specifies the user ID and password that is used to authenticate the creation of a new connection to the JCA resource adapter.

**Destination JNDI name**
This attribute specifies the JNDI name that the message-driven bean uses to look up the JMS destination in the JNDI namespace.

e. Optional: Specify **Destination Link** to enable message linking.

Message linking allows the routing of messages to a specific message-driven bean in a deployment. Message linking allows message flow to be orchestrated between components in the same application.

For a message to be consumed and processed by a message-driven bean, the<message-destination-link> element must be defined in the deployment descriptor associated with the message-driven bean. The destination identified by the <message-destination-link> element corresponds to the logical destination.

When the <message-destination-ref> includes a <message-destination-link> element, messages are consumed at that destination.

In order to get the message-driven bean to consume messages sent to a destination, you can declare a <message-destination-link> element in the deployment descriptor, or alternatively set it in the activation specification.

4. Assemble and package the application for deployment.

## Results

The result of this task is an EAR file, containing the message-driven bean, for the enterprise application that can be deployed in WebSphere Application Server.

## Example

The following example shows how to create the message-driven bean class. The example code shows how to access the text and the JMS **MessageID**, from a JMS message of type TextMessage. In this example, first the onMessage() method of a message-driven bean is used to unpack the incoming text message and to extract the text and message identifier; then a private putMessage method (defined within the same message bean class) is used to put the message onto another queue:

```
public void onMessage(javax.jms.Message msg)
{
        String text      = null;
        String messageID = null;

        try
        {
                text = ((TextMessage)msg).getText();

                System.out.println("senderBean.onMessage(), msg text2: "+text);
```

```
                //
                // store the message id to use as the Correlator value
                //
                messageID = msg.getJMSMessageID();

                // Call a private method to put the message onto another queue
                putMessage(messageID, text);
        }
        catch  (Exception err)
        {
                err.printStackTrace();
        }
        return;
}
```

### What to do next

After you have developed an enterprise application to use message-driven beans, configure and deploy the application. For example, define activation specifications for the message-driven beans and, optionally, change the deployment descriptor attributes for the application. For more information, see “Deploying an enterprise application to use message-driven beans with JCA 1.5-compliant resources” on page 697 and “Deploying an enterprise application to use message-driven beans with listener ports” on page 699.

## Deploying an enterprise application to use message-driven beans with JCA 1.5-compliant resources

Message-driven beans can be configured as listeners on a Java EE Connector Architecture (JCA) 1.5 resource adapter, such as the default messaging provider or the WebSphere MQ messaging provider in WebSphere Application Server.

### Before you begin

This task assumes that you have an EAR file that contains an enterprise application, developed as a message-driven bean, that can be deployed in WebSphere Application Server.

**Note:** You can continue to deploy message-driven beans against a listener port. You might want to do this for compatability with existing message-driven bean applications. However, listener ports are stabilized, and you should plan to migrate all your message-driven beans to use JCA 1.5-compliant resources.

### About this task

You deploy message-driven beans against JCA 1.5-compliant resources, and configure the resources as deployment descriptor attributes and (for EJB 3) as annotations.

### Procedure

1. For each message-driven bean in the application, create a J2C activation specification.
2. For each message-driven bean in the application, configure the J2C deployment attributes, as described in “Configuring deployment attributes for a message-driven bean against JCA 1.5-compliant resources” on page 697.
3. Use the WebSphere Application Server administrative console to install the application.

# Configuring deployment attributes for a message-driven bean against JCA 1.5-compliant resources

You can configure the message-driven bean deployment attributes for a Java EE Connector Architecture (JCA) 1.5-compliant enterprise application, to override the deployment attributes defined within the application EAR file.

## Before you begin

This task assumes that you have an EAR file that contains an enterprise application, developed as a message-driven bean, that can be deployed in WebSphere Application Server.

**Note:** You can continue to configure message-driven beans against a listener port. You might want to do this for compatability with existing message-driven bean applications. However, listener ports are stabilized, and you should plan to migrate all your message-driven beans to use JCA 1.5-compliant resources.

## About this task

You configure the deployment attributes of a message-driven bean application by using an assembly tool. Detailed steps given in this task are for Rational Application Developer, but other tools have very similar steps.

## Procedure

1. Start your assembly tool.
2. Edit the application EAR file. For example, use the Rational Application Developer import wizard to import the EAR file into the assembly tool. To start the import wizard:
   a. Click **File** > **Import** > **EAR file**.
   b. Click **Next**, then select the EAR file.
   c. Click **Finish**.
3. Open the deployment attributes for editing. In the Java EE Hierarchy view, right-click the EJB module for the message-driven bean then click **Open With** > **Deployment Descriptor Editor**. A property dialog notebook for the message-driven bean is displayed in the property pane.
4. Review and, if needed, change the deployment attributes.
   a. In the property pane, select the **Bean** tab.
   b. Under **Activation Configuration**, review the attributes.

      **Note:** For EJB 3 message-driven beans, you can instead use an EJB 3 annotation to configure the activation configuration properties. Do not use an EJB 3 annotation to change or replace what is specified in the bean deployment descriptor. If an activation configuration property is specified in both places, the value used is the one that is given in the deployment descriptor.

      **`acknowledgeMode`**
      This attribute determines how the session acknowledges any messages it receives.
      **Auto Acknowledge**
      The session automatically acknowledges delivery of each message.
      **Dups OK Acknowledge**
      The session lazily acknowledges the delivery of messages. This setting is likely to result in the delivery of some duplicate messages if JMS fails, so it should be used only by consumer applications that are tolerant of duplicate messages.

      **`destinationType`**
      This attribute determines whether the message-driven bean uses a queue or topic destination.

**Queue**
The message-driven bean uses a queue destination.
**Topic** The message-driven bean uses a topic destination.

**subscriptionDurability**
This attribute determines whether a JMS topic subscription is durable or nondurable.
**Durable**
A subscriber registers a durable subscription with a unique identity that is retained by JMS. Subsequent subscriber objects with the same identity resume the subscription in the state it was left in by the earlier subscriber. If there is no active subscriber for a durable subscription, JMS retains the subscription messages until they are received by the subscription or until they expire.
**Nondurable**
Nondurable subscriptions last for the lifetime of their subscriber object. This means that a client sees the messages published on a topic only while its subscriber is active. If the subscriber is not active, the client is missing messages published on its topic.

A nondurable subscriber can only be used in the same transactional context (for example, a global transaction or an unspecified transaction context) that existed when the subscriber was created.

**messageSelector**
This attribute determines the JMS message selector that is used to select which messages the message-driven bean receives. For example:

```
JMSType='car' AND color='blue' AND weight>2500
```

The selector string can refer to fields in the JMS message header and fields in the message properties. Message selectors cannot reference message body values.

c. Specify bindings deployment attributes.

Under **WebSphere Bindings**, select the **JCA Adapter** option then specify the bindings deployment attributes:
**ActivationSpec JNDI name**
This attribute specifies the JNDI name of the activation specification that is used to deploy this message-driven bean. This name must match the name of an activation specification that you define to WebSphere Application Server.
**ActivationSpec Authorization Alias**
This attribute specifies the name of an authentication alias used for authentication of connections to the JCA resource adapter. An authentication alias specifies the user ID and password that is used to authenticate the creation of a new connection to the JCA resource adapter.
**Destination JNDI name**
This attribute specifies the JNDI name that the message-driven bean uses to look up the JMS destination in the JNDI namespace.

5. Save your changes to the deployment descriptor:
   a. Close the deployment descriptor editor.
   b. When prompted, click **Yes** to indicate that you want to save changes to the deployment descriptor.
6. Verify the archive files.
7. From the pop-up menu for the project, click **Deploy** to generate EJB deployment code.
8. Optional: Test your completed module on a WebSphere Application Server installation.

Right-click a module, click **Run on Server**, then follow the instructions in the displayed wizard.

**Restriction:** **Run on Server** works on the Windows, Linux/Intel, and AIX operating systems only. You cannot deploy remotely to a WebSphere Application Server installation on a UNIX operating system such as Solaris.

**Important:** Use **Run on Server** for unit testing only. When an application is published remotely, the assembly tool overwrites the server configuration file for that server. Do not use on production servers.

### What to do next

After assembling your application, use a systems management tool to deploy the EAR file onto the application server that will run the application; for example, use the administrative console as described in Deploying and managing applications.

## Deploying an enterprise application to use message-driven beans with listener ports

Define the listener ports for your application. For each message-driven bean in the application, configure the deployment attributes to match the listener port definitions. Install the application, specifying the name of the listener port to use for late responses.

### Before you begin

Listener ports are stabilized. For more information, read the article on stabilized features. You should only deploy your application against a listener port for compatability with existing message-driven bean applications. Otherwise, you should deploy your application against JCA 1.5-compliant resources.

If you have existing message-driven beans that use the WebSphere MQ messaging provider (or a compliant third-party JMS provider) with listener ports, and instead you want to use EJB 3 message-driven beans with listener ports, these new beans can continue to use the same messaging provider.

This task assumes that you have an EAR file, which contains an enterprise application developed as a message-driven bean, that can be deployed in WebSphere Application Server.

### Procedure

1. Define the listener ports for your application, by using the WebSphere Application Server administrative console as described in Creating a new listener port.
2. For each message-driven bean in the application, configure the deployment attributes to match the listener port definitions, as described in “Configuring deployment attributes for a message-driven bean against a listener port” on page 700.
3. Install the application, as described in Installing enterprise application files with the console.

   When you install the application, you are prompted to specify the name of the listener port that the application is to use for late responses. Select the listener port, then click **OK**.

## Configuring deployment attributes for a message-driven bean against a listener port

You can configure the message-driven beans deployment attributes for an enterprise bean, to override the deployment attributes defined within the application EAR file.

### Before you begin

Listener ports are stabilized. For more information, read the article on stabilized features. You should only configure your application against a listener port for compatability with existing message-driven bean applications. Otherwise, you should configure your application against JCA 1.5-compliant resources.

If you have existing message-driven beans that use the WebSphere MQ messaging provider (or a compliant third-party JMS provider) with listener ports, and instead you want to use EJB 3 message-driven beans with listener ports, these new beans can continue to use the same messaging provider.

This task assumes that you have an EAR file that contains an enterprise application, developed as a message-driven bean, that can be deployed in WebSphere Application Server.

## About this task

You configure the deployment attributes of a message-driven bean application by using an assembly tool. Detailed steps given in this task are for Rational Application Developer, but other tools have very similar steps.

## Procedure

1. Start your assembly tool.
2. Edit the application EAR file. For example, use the Rational Application Developer import wizard to import the EAR file into the assembly tool. To start the import wizard:
   a. Click **File** > **Import** > **EAR file**.
   b. Click **Next**, then select the EAR file.
   c. Click **Finish**.
3. Open the deployment attributes for editing. In the Java EE Hierarchy view, right-click the EJB module for the message-driven bean then click **Open With** > **Deployment Descriptor Editor**. A property dialog notebook for the message-driven bean is displayed in the property pane.
4. Specify general deployment attributes.
   a. In the property pane, select the **Bean** tab.
   b. On the main panel, configure the **Transaction type** attribute.

      This attribute determines whether the message-driven bean manages its own transactions, or whether the container manages transactions on behalf of the bean.
      **Bean** The message-driven bean manages its own transactions.
      **Container**
      The container manages transactions on behalf of the bean.
5. Under **Activation Configuration**, review the following attributes:

   **Note:** For EJB 3 message-driven beans, you can instead use an EJB 3 annotation to configure the activation configuration properties. Do not use an EJB 3 annotation to change or replace what is specified in the bean deployment descriptor. If an activation configuration property is specified in both places, the value used is the one that is given in the deployment descriptor.

   **`acknowledgeMode`**
   This attribute determines how the session acknowledges any messages it receives.
   **Auto Acknowledge**
   The session automatically acknowledges delivery of each message.
   **Dups OK Acknowledge**
   The session lazily acknowledges the delivery of messages. This setting is likely to result in the delivery of some duplicate messages if JMS fails, so it should be used only by consumer applications that are tolerant of duplicate messages.

   **`destinationType`**
   This attribute determines whether the message-driven bean uses a queue or topic destination.
   **Queue**
   The message-driven bean uses a queue destination.
   **Topic** The message-driven bean uses a topic destination.

   **`subscriptionDurability`**
   This attribute determines whether a JMS topic subscription is durable or nondurable.
   **Durable**
   A subscriber registers a durable subscription with a unique identity that is retained by JMS. Subsequent subscriber objects with the same identity resume the subscription in

the state it was left in by the earlier subscriber. If there is no active subscriber for a durable subscription, JMS retains the subscription messages until they are received by the subscription or until they expire.

**Nondurable**

Nondurable subscriptions last for the lifetime of their subscriber object. This means that a client sees the messages published on a topic only while its subscriber is active. If the subscriber is not active, the client is missing messages published on its topic.

A nondurable subscriber can only be used in the same transactional context (for example, a global transaction or an unspecified transaction context) that existed when the subscriber was created.

**messageSelector**

This attribute determines the JMS message selector that is used to select which messages the message-driven bean receives. For example:

```
JMSType='car' AND color='blue' AND weight>2500
```

The selector string can refer to fields in the JMS message header and fields in the message properties. Message selectors cannot reference message body values.

6. Specify the bindings deployment attribute.
   a. Under **WebSphere Bindings**, specify the following attribute:
      **Listener port name**
      Type the name of the listener port for this message-driven bean.
7. Save your changes to the deployment descriptor:
   a. Close the deployment descriptor editor.
   b. When prompted, click **Yes** to indicate that you want to save changes to the deployment descriptor.
8. Verify the archive files.
9. From the pop-up menu for the project, click **Deploy** to generate EJB deployment code.
10. Optional: Test your completed module on a WebSphere Application Server installation.
    Right-click a module, click **Run on Server**, then follow the instructions in the displayed wizard.

    **Restriction:** **Run on Server** works on the Windows, Linux/Intel, and AIX operating systems only. You cannot deploy remotely to a WebSphere Application Server installation on a UNIX operating system such as Solaris.

    **Important:** Use **Run on Server** for unit testing only. When an application is published remotely, the assembly tool overwrites the server configuration file for that server. Do not use on production servers.

## What to do next

After assembling your application, use a systems management tool to deploy the EAR file onto the application server that will run the application; for example, use the administrative console as described in Deploying and managing applications.

# Chapter 19. Developing Naming and directory

This page provides a starting point for finding information about naming support. Naming includes both server-side and client-side components. The server-side component is a Common Object Request Broker Architecture (CORBA) naming service (CosNaming). The client-side component is a Java Naming and Directory Interface (JNDI) service provider. JNDI is a core component in the Java Platform, Enterprise Edition (Java EE) programming model.

The WebSphere JNDI service provider can be used to interoperate with any CosNaming name server implementation. Yet WebSphere name servers implement an extension to CosNaming, and the JNDI service provider uses those WebSphere extensions to provide greater capability than CosNaming alone. Some added capabilities are binding and looking up of non-CORBA objects.

Java EE applications use the JNDI service provider supported by WebSphere Application Server to obtain references to objects related to server applications, such as enterprise bean (EJB) homes, which have been bound into a CosNaming name space.

## Developing applications that use JNDI

References to enterprise bean (EJB) homes and other artifacts such as data sources are bound to the WebSphere Application Server name space. These objects can be obtained through Java Naming and Directory Interface (JNDI). Before you can perform any JNDI operations, you need to get an initial context. You can use the initial context to look up objects bound to the name space.

### About this task

The following examples describe how to get an initial context and how to perform lookup operations.
- Getting the default initial context
- Getting an initial context by setting the provider URL property
- Setting the provider URL property to select a different root context as the initial context
- Looking up an EJB home with JNDI

In these examples, the default behavior of features specific to the WebSphere Application Server JNDI Context implementation is used.

The WebSphere Application Server JNDI context implementation includes special features. JNDI caching enhances performance of repeated lookup operations on the same objects. Name syntax options offer a choice of a name syntaxes, one optimized for typical JNDI clients, and one optimized for interoperability with CosNaming applications. Most of the time, the default behavior of these features is the preferred behavior. However, sometimes you should modify the behavior for specific situations.

JNDI caching and name syntax options are associated with a javax.naming.InitialContext instance. To select options for these features, set properties that are recognized by the WebSphere Application Server initial context factory. To set JNDI caching or name syntax properties which will be visible to the initial context factory, do the following:

### Procedure

1. Optional: Configure JNDI caches

   JNDI caching can greatly increase performance of JNDI lookup operations. By default, JNDI caching is enabled. In most situations, this default is the desired behavior. However, in specific situations, use the other JNDI cache options.

© IBM Corporation 2009

Objects are cached locally as they are looked up. Subsequent lookups on cached objects are resolved locally. However, cache contents can become stale. This situation is not usually a problem, since most objects you look up do not change frequently. If you need to look up objects which change relatively frequently, change your JNDI cache options.

JNDI clients can use several properties to control cache behavior.

You can set properties:

- From the command line by entering the actual string value. For example:

  ```
  java -Dcom.ibm.websphere.naming.jndicache.maxentrylife=1440
  ```

- In a `jndi.properties` file by creating a file named `jndi.properties` as a text file with the desired properties settings. For example:

  ```
  ...
  com.ibm.websphere.naming.jndicache.cacheobject=none
  ...
  ```

  If you use this technique, be aware that other instances of the `jndi.properties` file might exist in the classpath, and might contain conflicting property settings. Property settings are determined by the order in which the class loader picks up the `jndi.properties` files. There is no way to control the order that the class loader uses to locate files in the classpath. WebSphere Application Server does not initially contain or create any `jndi.properties` files that set the com.ibm.websphere.naming.jndicache.cacheobject property.

- Within a Java program by using the PROPS.JNDI_CACHE* Java constants, defined in the `com.ibm.websphere.naming.PROPS` file. The constant definitions follow:

  ```
  public static final String JNDI_CACHE_OBJECT =
   "com.ibm.websphere.naming.jndicache.cacheobject";
  public static final String JNDI_CACHE_OBJECT_NONE      = "none";
  public static final String JNDI_CACHE_OBJECT_POPULATED = "populated";
  public static final String JNDI_CACHE_OBJECT_CLEARED   = "cleared";
  public static final String JNDI_CACHE_OBJECT_DEFAULT   =
   JNDI_CACHE_OBJECT_POPULATED;

  public static final String JNDI_CACHE_NAME =
   "com.ibm.websphere.naming.jndicache.cachename";
  public static final String JNDI_CACHE_NAME_DEFAULT = "providerURL";

  public static final String JNDI_CACHE_MAX_LIFE =
   "com.ibm.websphere.naming.jndicache.maxcachelife";
  public static final int    JNDI_CACHE_MAX_LIFE_DEFAULT = 0;

  public static final String JNDI_CACHE_MAX_ENTRY_LIFE =
   "com.ibm.websphere.naming.jndicache.maxentrylife";
  public static final int    JNDI_CACHE_MAX_ENTRY_LIFE_DEFAULT = 0;
  ```

  To use the previous properties in a Java program, add the property setting to a hashtable and pass it to the InitialContext constructor as follows:

  ```
  java.util.Hashtable env = new java.util.Hashtable();
  ...

  // Disable caching
  env.put(PROPS.JNDI_CACHE_OBJECT, PROPS.JNDI_CACHE_OBJECT_NONE); ...
  javax.naming.Context initialContext = new javax.naming.InitialContext(env);
  ```

Following are examples that illustrate how you can use JNDI cache properties to achieve the desired cache behavior. Cache properties take effect when an InitialContext object is constructed.

**Example: Controlling JNDI cache behavior from a program**

```
import java.util.Hashtable;
import javax.naming.InitialContext;
import javax.naming.Context;
import com.ibm.websphere.naming.PROPS;

/*****
 Caching discussed in this section pertains to the WebSphere Application Server initial context factory.
 Assume the property, java.naming.factory.initial, is set to
 "com.ibm.websphere.naming.WsnInitialContextFactory" as a java.lang.System property.
*****/

Hashtable env;
```

```
Context ctx;

// To clear a cache:

env = new Hashtable();
env.put(PROPS.JNDI_CACHE_OBJECT, PROPS.JNDI_CACHE_OBJECT_CLEARED);
ctx = new InitialContext(env);

// To set a cache's maximum cache lifetime to 60 minutes:

env = new Hashtable();
env.put(PROPS.JNDI_CACHE_MAX_LIFE, "60");
ctx = new InitialContext(env);

// To turn caching off:

env = new Hashtable();
env.put(PROPS.JNDI_CACHE_OBJECT, PROPS.JNDI_CACHE_OBJECT_NONE);
ctx = new InitialContext(env);

// To use caching and no caching:

env = new Hashtable();
env.put(PROPS.JNDI_CACHE_OBJECT, PROPS.JNDI_CACHE_OBJECT_POPULATED);
ctx = new InitialContext(env);
env.put(PROPS.JNDI_CACHE_OBJECT, PROPS.JNDI_CACHE_OBJECT_NONE);
Context noCacheCtx = new InitialContext(env);

Object o;

// Use caching to look up home, since the home should rarely change.
o = ctx.lookup("com/mycom/MyEJBHome");
// Narrow, etc. ...

// Do not use cache if data is volatile.
o = noCacheCtx.lookup("com/mycom/VolatileObject");
// ...
```

**Example: Looking up a JavaMail session with JNDI**

The following example shows a lookup of a JavaMail resource:

```
// Get the initial context as shown above
...
Session session =
     (Session) initialContext.lookup("java:comp/env/mail/MailSession");
```

2. Optional: Specify the name syntax

   *INS syntax* is designed for JNDI clients that need to interoperate with CORBA applications. This syntax allows a JNDI client to make the proper mapping to and from a CORBA name. INS syntax is very similar to the JNDI syntax with the additional special character, dot (.). Dots are used to delimit the id and kind fields in a name component. A dot is interpreted literally when it is escaped. Only one unescaped dot is allowed in a name component. A name component with a non-empty id field and empty kind field is represented with only the id field value and must not end with an unescaped dot. An empty name component (empty id and empty kind field) is represented with a single unescaped dot. An empty string is not a valid name component representation.

   *JNDI name syntax* is the default syntax and is suitable for typical JNDI clients. This syntax includes the following special characters: forward slash (/) and backslash (\). Components in a name are delimited by a forward slash. The backslash is used as the escape character. A forward slash is interpreted literally if it is escaped, that is, preceded by a backslash. Similarly, a backslash is interpreted literally if it is escaped.

   Most WebSphere applications use JNDI to look up EJB objects and do not need to look up objects bound by CORBA applications. Therefore, the default name syntax used for JNDI names is the most convenient. If your application needs to look up objects bound by CORBA applications, you may need to change your name syntax so that all CORBA CosNaming names can be represented.

   JNDI clients can set the name syntax by setting a property. The property setting is applied by the initial context factory when you instantiate a new java.naming.InitialContext object. Names specified in JNDI operations on the initial context are parsed according to the specified name syntax.

You can set the property:

- From a command line, enter the actual string value. For example:

```
java -Dcom.ibm.websphere.naming.name.syntax=ins
```

- Create a file named `jndi.properties` as a text file with the desired properties settings. For example:

```
...
com.ibm.websphere.naming.name.syntax=ins
...
```

  If you use this technique, be aware that other instances of the `jndi.properties` file might exist in the classpath, and might contain conflicting property settings. Property settings are determined by the order in which the class loader picks up the `jndi.properties` files. There is no way to control the order that the class loader uses to locate files in the classpath. WebSphere Application Server does not initially contain or create any `jndi.properties` files that set the com.ibm.websphere.naming.name.syntax property.

- Use the PROPS.NAME_SYNTAX* Java constants, defined in the `com.ibm.websphere.naming.PROPS` file, in a Java program. The constant definitions follow:

```
public static final String NAME_SYNTAX =
    "com.ibm.websphere.naming.name.syntax";
public static final String NAME_SYNTAX_JNDI = "jndi";
public static final String NAME_SYNTAX_INS  = "ins";
```

  To use the previous properties in a Java program, add the property setting to a hashtable and pass it to the InitialContext constructor as follows:

```
java.util.Hashtable env = new java.util.Hashtable();
...
env.put(PROPS.NAME_SYNTAX, PROPS.NAME_SYNTAX_INS); // Set name syntax to INS
...
javax.naming.Context initialContext = new javax.naming.InitialContext(env);
```

**Example: Setting the syntax used to parse name strings**

The name syntax property can be passed to the InitialContext constructor through its parameter, in the System properties, or in a `jndi.properties` file. The initial context and any contexts looked up from that initial context parse name strings based on the specified syntax.

The following example shows how to set the name syntax to make the initial context parse name strings according to INS syntax.

```
...
import java.util.Hashtable;
import javax.naming.Context;
import javax.naming.InitialContext;
import com.ibm.websphere.naming.PROPS; // WebSphere naming constants
...
Hashtable env = new Hashtable();
env.put(Context.INITIAL_CONTEXT_FACTORY,
      "com.ibm.websphere.naming.WsnInitialContextFactory");
env.put(Context.PROVIDER_URL, ...);
env.put(PROPS.NAME_SYNTAX, PROPS.NAME_SYNTAX_INS);
Context initialContext = new InitialContext(env);
// The following name maps to a CORBA name component as follows:
//    id = "a.name", kind = "in.INS.format"
// The unescaped dot is used as the delimiter.
// Escaped dots are interpreted literally.
java.lang.Object o = initialContext.lookup("a\\.name.in\\.INS\\.format");
...
```

INS name syntax requires that embedded periods (.) in a name such as `in.INS.format` be escaped using a backslash character (\). In a Java String literal, a backslash character (\) must be escaped with another backslash character (\\).

3. Optional: Disable host name normalization

   References to host names, IP addresses, and `localhost` in provider URLs are typically normalized. The format of a normalized host name is the fully-qualified form of the host name. Host name normalization improves system efficiency because it enables the same JNDI cache to be used for a given bootstrap host regardless of the format of the reference in the provider URL. For example, host name normalization enables the same JNDI cache to be used for `myhost`, `myhost.mydomain.com`, and `localhost` references if all of these references refer to the same host.

Because normalized host names are cached, subsequent normalizations execute more quickly. In some network environments, domain name lookup data changes dynamically, causing the cached host name normalization data to become stale. In such environments, you might need to disable hostname normalization. When you disable host normalization, host name and IP addresses are used as is. References to `localhost` typically resolve to the loopback address, 127.0.0.1.

JNDI clients can disable host name normalization by setting a property. The property setting is applied by the initial context factory when you instantiate a new java.naming.InitialContext object.

Use one of the following techniques to set this property:

- You can enter the actual string value from a command line. For example:

  ```
  java -Dcom.ibm.websphere.naming.hostname.normalizer=...none...
  ```

- You can create a file named `jndi.properties` as a text file with the desired properties settings. For example:

  ```
  ...
  com.ibm.websphere.naming.hostname.normalizer=...none...
  ...
  ```

  If you use this technique, be aware that other instances of the `jndi.properties` file might exist in the classpath, and might contain conflicting property settings. Property settings are determined by the order in which the class loader picks up the `jndi.properties` files. There is no way to control the order that the class loader uses to locate files in the classpath. WebSphere Application Server does not initially contain or create any `jndi.properties` files that set the com.ibm.websphere.naming.hostname.normalizer property.

- You can use the PROPS.HOSTNAME_NORMALIZER* Java constants in a Java program. These Java constants are defined in the com.ibm.websphere.naming.PROPS file. Following are the constant definitions to specify if you use this technique:

  ```
  public static final String HOSTNAME_NORMALIZER =
      "com.ibm.websphere.naming.hostname.normalizer";
  public static final String HOSTNAME_NORMALIZER_NONE = "...none...;
  ```

  To use these definitions in a Java program, add the property setting to a hashtable and pass it to the InitialContext constructor:

  ```
  java.util.Hashtable env = new java.util.Hashtable();
  ...
  env.put(PROPS.HOSTNAME_NORMALIZER, PROPS.HOSTNAME_NORMALIZER_NONE);
      // Disable hostname normalization
  ...
  javax.naming.Context initialContext =
     new javax.naming.InitialContext(env);
  ```

**Example: Disabling host name normalization**

You can pass the host name normalizer property to the InitialContext constructor through the InitialContext constructor parameter in the system properties file, or in a `jndi.properties` file. The initial context and any future contexts looked up from that initial context use this property setting.

The following example shows how to disable host name normalization.

```
...
import java.util.Hashtable;
import javax.naming.Context;
import javax.naming.InitialContext;
import com.ibm.websphere.naming.PROPS; // WebSphere naming constants
...
Hashtable env = new Hashtable();
env.put(Context.INITIAL_CONTEXT_FACTORY,
      "com.ibm.websphere.naming.WsnInitialContextFactory");
env.put(Context.PROVIDER_URL, ...);
env.put(PROPS.HOSTNAME_NORMALIZER, PROPS.HOSTNAME_NORMALIZER_NONE);
Context initialContext = new InitialContext(env);
java.lang.Object o = initialContext.lookup(...);
...
```

## Example: Getting the default initial context

There are various ways for a program to get the default initial context.

The following example gets the default initial context. Note that no provider URL is passed to the javax.naming.InitialContext constructor.

```
...
import javax.naming.Context;
import javax.naming.InitialContext;
...
Context initialContext = new InitialContext();
...
```

The default initial context returned depends the runtime environment of the Java Naming and Directory Interface (JNDI) client. Following are the initial contexts returned in the various environments:

**Thin client**
The initial context is the server root context of the server running on the local host at port 2809.

**Pure client**
The initial context is the context specified by the java.naming.provider.url property passed to launchClient command with the -CCD command line parameter. The context usually is the server root context of the server at the address specified in the URL, although it is possible to construct a corbaname or corbaloc URL which resolves to some other context.

If no provider URL is specified, it is the server root context of the server running on the host and port specified by the `-CCproviderURL`, or `-CCBootstrapHost` and `-CCBootstrapPort` command line parameters. The default host is the local host, and the default port is 2809.

**Server process**
The initial context is the server root context for that process.

Even though no provider URL is explicitly specified in the above example, the InitialContext constructor might find a provider URL defined in other places that it searches for property settings.

Users of properties which affect ORB initialization should read the rest of this section for a deeper understanding of exactly how initial contexts are obtained.

## Determining which server is used to obtain the initial context

WebSphere Application Server name servers are CORBA CosNaming name servers, and the product provides a CosNaming JNDI plug-in implementation for JNDI clients to perform naming operations on product namespaces. The CosNaming plug-in implementation is selected through a JNDI property that is passed to the InitialContext constructor. This property is `java.naming.factory.initial`, and it specifies the initial context factory implementation to use to obtain an initial context. The factory returns a javax.naming.Context instance, which is part of its implementation.

The initial context factory, `com.ibm.websphere.naming.WsnInitialContextFactory`, is typically used by applications to perform JNDI operations. The WebSphere Application Server runtime environment is set up to use this initial context factory if one is not specified explicitly by the JNDI client. When the initial context factory is invoked, an *initial context* is obtained. The following paragraphs explain how the initial context factory obtains the initial context in client and server environments.

- **Registration of initial references in server processes**

  Every WebSphere Application Server has an ORB used to receive and dispatch invocations on objects running in that server. Services running in the server process can register initial references with the ORB. Each initial reference is registered under a key, which is a string value. An initial reference can be any CORBA object. WebSphere Application Server name servers register several initial contexts as initial references under predefined keys. Each name server initial reference is an instance of the interface org.omg.CosNaming.NamingContext.
- **Obtaining initial references in pure client processes**

  Pure JNDI clients, that is, JNDI clients which are not running in a WebSphere Application Server process, also have an ORB instance. This client ORB instance can be passed to the InitialContext

constructor, but typically the initial context factory creates and initializes the client ORB instance transparently. A client ORB can be initialized with initial references, but the initial references most likely resolve to objects running in some server. The initial context factory does not define any default initial references when it initializes an ORB. If the `resolve_initial_references` method is invoked on the client ORB when no initial references have been configured, the method invocation fails. This condition is typical for pure client processes. To obtain an initial NamingContext reference, the initial context factory must invoke `string_to_object` with an IIOP type CORBA object URL, such as `corbaloc:iiop:myhost:2809`. The URL specifies the address of the server from which to obtain the initial context. The host and port information is extracted from the provider URL passed to the InitialContext constructor.

AIX HP-UX Linux Solaris Windows If no provider URL is defined, the WebSphere Application Server initial context factory uses the default provider URL of `corbaloc:iiop:localhost:2809`.

The `string_to_object` ORB method resolves the URL and communicates with the target server ORB to obtain the initial reference.

- **Obtaining initial references in server processes**

  If the JNDI client is running in a WebSphere Application Server process, the initial context factory obtains a reference to the server ORB instance if the JNDI client does not provide an ORB instance. Typically, JNDI clients running in server processes use the server ORB instance; that is, they do not pass an ORB instance to the InitialContext constructor. The name server which is running in the server process sets a provider URL as a java.lang.System property to serve as the default provider URL for all JNDI clients in the process. This default provider URL is `corbaloc:rir:/NameServiceServerRoot`. This URL resolves to the server root context for that server. (The URL is equivalent to invoking `resolve_initial_references` on the ORB with a key of NameServiceServerRoot. The name server registers the server root context as an initial reference under that key.)

- **Understanding the legacy ORB protocol**

  Releases previous to WebSphere Application Server Version 5 used a different ORB implementation, which used a legacy protocol in contrast with the Interoperable Name Service (INS) protocol now used. This change has affected the implementation of the initial context factory. **Certain types of pure clients can experience different behavior when getting initial JNDI contexts as compared to previous releases of WebSphere Application Server**. This behavior is discussed in more detail below.

  The following ORB properties are used with the legacy ORB protocol for ORB initialization and are now deprecated:
  – com.ibm.CORBA.BootstrapHost
  – com.ibm.CORBA.BootstrapPort

  The new INS ORB is different in a major respect, in that it exhibits no default behavior if no initial references are defined.

  AIX HP-UX Linux Solaris Windows In the legacy ORB, the bootstrap host and port values defaulted to `localhost` and `900`.

  All initial references were obtained from the server running on the bootstrap host and port. So, if the ORB user provided no bootstrap host and port, all initial references are resolved from the server running on the local host at port 900. The INS ORB has no concept of bootstrap host or bootstrap port. All initial references are defined independently. That is, different initial references could resolve to different servers. If `ORB.resolve_initial_references` is invoked with a key such that the ORB is not initialized with an initial reference having that key, the call fails.

  In releases previous to Version 5, the initial context factory invoked `resolve_initial_references` on the ORB in the absence of any provider URL. This action succeeded if a name server at the default bootstrap host and port was running. In the current release, with the INS ORB, this would fail. (Actually, the ORB would fall back to the legacy protocol during the deprecation period, but when the legacy protocol is no longer supported, the operation would fail.)

  AIX HP-UX Linux Solaris Windows The initial context factory now uses a default provider URL of `corbaloc:iiop:localhost:2809`, and invokes `string_to_object` with the provider URL.

This operation preserves the behavior that pure clients in previous releases experienced when they set no ORB bootstrap properties or provider URL. **However, this different initial context factory implementation changes the behavior experienced by certain legacy pure clients, which do not specify a provider URL**:
– Clients which set the ORB bootstrap properties listed above when getting an initial context.
– Clients which supply their own ORB instance to the InitialContext constructor.

There are two ways to circumvent this change of behavior:

– Always specify an IIOP type provider URL. This approach does not depend on the bootstrap host and port properties and continues to work when support for the bootstrap host and port properties is removed. For example, you can express bootstrap host and port property values of `myHost` and `2809`, respectively, as `corbaloc:iiop:myHost:2809`.
– Use an rir type provider URL:
  - Specify `corbaloc:rir:/NameServiceServerRoot` if the ORB is initialized to use a Version 5 server as the bootstrap server.
  - Specify `corbaname:rir:/NameService#domain/legacyRoot` if the ORB is initialized to use a Version 4.0.x server as the bootstrap server.
  - Specify `corbaloc:rir:/NameService` if the ORB is initialized to use a server other than a Version 5 or 4.0.x server as the bootstrap server.

  URLs of this type are equivalent to invoking `resolve_initial_references` on the ORB with the specified key. If the bootstrap host and port properties are being used to initialize the ORB, this approach will not work when the bootstrap and host properties are no longer supported.

- **The InitialContext constructor search order for JNDI properties**

  If the code snippet shown at the beginning of this section is executed by an application, the bootstrap server depends on the value of the property, java.naming.provider.url.

  AIX HP-UX Linux Solaris Windows If the property is not set (in server processes the default value is set as a system property), the default host of `localhost` and default port of `2809` are used as the address of the server from which to obtain the initial context.

  The JNDI specification describes where the InitialContext constructor looks for java.naming.provider.url property settings, but briefly, the property is picked up from the following places in the order shown:

  **InitialContext constructor**
  This does not apply to the above example because the example uses the empty InitalContext constructor.

  **System environment**
  You can add JNDI properties to the system environment as an option on the Java command invocation and by program code. The recommended way to set the provider URL in the system environment is as an option supplied to the Java command invocation. Setting the provider URL in this manner is not temporal, so that getting a default initial context will always yield the same result. It is generally recommended that program code not set the provider URL property in the system environment because as a side-effect, this could adversely affect other, possibly unrelated, code running elsewhere in the same process.

  **`jndi.properties` file**
  There may be many `jndi.properties` files that are within the scope of the class loader in effect. All `jndi.properties` files are used for setting JNDI properties, but the provider URL setting is determined by the first `jndi.properties` file returned by the class loader.

## Example: Getting an initial context by setting the provider URL property

In general, Java Naming and Directory Interface (JNDI) clients should assume the correct environment is already configured so there is no need to explicitly set property values and pass them to the `InitialContext` constructor. However, a JNDI client might need to access a namespace other than the one identified in its environment. In this case, it is necessary to explicitly set the java.naming.provider.url (provider URL) property used by the `InitialContext` constructor. A provider URL contains bootstrap server

information that the initial context factory can use to obtain an initial context. Any property values passed in directly to the `InitialContext` constructor take precedence over settings of those same properties found elsewhere in the environment.

You can use two different provider URL forms with theWebSphere Application Server initial context factory:
- A CORBA object URL
- An IIOP URL

CORBA object URLs are more flexible than IIOP URLs and are the recommended URL format to use. CORBA object URLs are part of the OMG CosNaming Interoperable Naming Specification. A corbaname URL, for example, can include initial context and lookup name information and can be used as a lookup name without the need to explicitly obtain another initial context. The IIOP URLs are the legacy JNDI format, but are still supported by the WebSphere Application Server initial context factory.

The following examples illustrate the use of these URLs.
- "Using a CORBA object URL"
- "Using a CORBA object URL from a non-WebSphere Application Server JNDI implementation"
- "Using an IIOP URL" on page 928

## Using a CORBA object URL

This example shows a CORBA object URL.

```
...
import java.util.Hashtable;
import javax.naming.Context;
import javax.naming.InitialContext;
...
Hashtable env = new Hashtable();
env.put(Context.INITIAL_CONTEXT_FACTORY,
     "com.ibm.websphere.naming.WsnInitialContextFactory");
env.put(Context.PROVIDER_URL, "corbaloc:iiop:myhost.mycompany.com:2809");
Context initialContext = new InitialContext(env);
...
```

## Using a CORBA object URL from a non-WebSphere Application Server JNDI implementation

Initial context factories for CosNaming JNDI plug-in implementations other than the WebSphere Application Server initial context factory most likely obtain an initial context using the object key, `NameService`. When you use such a context factory to obtain an initial context from a WebSphere Application Server name server, the initial context is the cell root context. Since system artifacts such as EJB homes associated with a server are bound under the server's server root context, names used in JNDI operations must be qualified. If you want to use relative names, ensure your initial context is the server root context under which the target object is bound. In order to make the server root context the initial context, specify a corbaloc provider URL with an object key of `NameServiceServerRoot`.

This example shows a CORBA object type URL from a non-WebSphere Application Server JNDI implementation. This example assumes full CORBA object URL support by the non-WebSphere Application Server JNDI implementation. The object key of `NameServiceServerRoot` is specified so that the initial context will be the specified server's server root context.

```
...
import java.util.Hashtable;
import javax.naming.Context;
import javax.naming.InitialContext;
...
Hashtable env = new Hashtable();
env.put(Context.INITIAL_CONTEXT_FACTORY,
      "com.somecompany.naming.TheirInitialContextFactory");
```

```
env.put(Context.PROVIDER_URL,
      "corbaname:iiop:myhost.mycompany.com:9810/NameServiceServerRoot");
Context initialContext = new InitialContext(env);
...
```

If qualified names are used, you can use the default key of `NameService`.

### Using an IIOP URL

The IIOP type of URL is a legacy format which is not as flexible as CORBA object URLs. However, URLs of this type are still supported. The following example shows an IIOP type URL as the provider URL.

```
...
import java.util.Hashtable;
import javax.naming.Context;
import javax.naming.InitialContext;
...
Hashtable env = new Hashtable();
env.put(Context.INITIAL_CONTEXT_FACTORY,
     "com.ibm.websphere.naming.WsnInitialContextFactory");
env.put(Context.PROVIDER_URL, "iiop://myhost.mycompany.com:2809");
Context initialContext = new InitialContext(env);
...
```

## Example: Setting the provider URL property to select a different root context as the initial context

Each server contains its own server root context, and, when bootstrapping to a server, the server root is the default initial JNDI context. Most of the time, this default is the desired initial context, since system artifacts such as EJB homes are bound there. However, other root contexts exist, which can contain bindings of interest. It is possible to specify a provider URL to select other root contexts.

Examples for selecting other root contexts follow:

- Initial root contexts with a CORBA object URL
- Initial root contexts with the namespace root property

### Selecting the initial root context with a CORBA object URL

There are several object keys registered with the bootstrap server that you can use to select the root context for the initial context. To select a particular root context with a CORBA object URL object key, set the object key to the corresponding value. The default object key is NameService. Using JNDI yields the server root context. A table that lists the different root contexts and their corresponding object key follows:

| Root Context | CORBA Object URL Object Key |
|---|---|
| **Server Root** | NameServiceServerRoot |
| **Cell Persistent Root** | NameServiceCellPersistentRoot |
| **Cell Root** | NameServiceCellRoot |
| **Node Root** | NameServiceNodeRoot |

The following example shows the use of a corbaloc URL with the object key set to select the cell persistent root context as the initial context.

```
...
import java.util.Hashtable;
import javax.naming.Context;
import javax.naming.InitialContext;
...
Hashtable env = new Hashtable();
env.put(Context.INITIAL_CONTEXT_FACTORY,
      "com.ibm.websphere.naming.WsnInitialContextFactory");
```

```
env.put(Context.PROVIDER_URL,
      "corbaloc:iiop:myhost.mycompany.com:2809/NameServiceCellPersistentRoot");
Context initialContext = new InitialContext(env);
...
```

### Selecting the initial root context with the namespace root property

You can also select the initial root context by passing a namespace root property setting to the InitialContext constructor. Generally, the object key setting described above is sufficient. Sometimes a property setting is preferable. For example, you can set the root context property on the Java invocation to make which server root is being used as the initial context transparent to the application. The default server root property setting is `defaultroot`, which yields the server root context.

| Root Context | Namespace Root Property Value |
|---|---|
| **Server Root** | bootstrapserverroot |
| **Cell Persistent Root** | cellpersistentroot |
| **Cell Root** | cellroot |
| **Node Root** | bootstrapnoderoot |

The initial context factory ignores the namespace root property if the provider URL contains an object key other than `NameService`.

The following example shows use of the namespace root property to select the cell persistent root context as the initial context. Note that available constants are used instead of hard-coding the property name and value.

```
...
import java.util.Hashtable;
import javax.naming.Context;
import javax.naming.InitialContext;
import com.ibm.websphere.naming.PROPS;
...
Hashtable env = new Hashtable();
env.put(Context.INITIAL_CONTEXT_FACTORY,
      "com.ibm.websphere.naming.WsnInitialContextFactory");
env.put(Context.PROVIDER_URL, "corbaloc:iiop:myhost.mycompany.com:2809");
env.put(PROPS.NAME_SPACE_ROOT, PROPS.NAME_SPACE_ROOT_CELL_PERSISTENT);
Context initialContext = new InitialContext(env);
...
```

## Example: Looking up an EJB home or business interface with JNDI

Most applications that use Java Naming and Directory Interface (JNDI) run in a container. Some do not. The name used to look up an object depends on whether or not the application is running in a container. Sometimes it is more convenient for an application to use a corbaname URL as the lookup name. Container-based JNDI clients and thin Java clients can use a corbaname URL.

The following examples show how to perform JNDI lookups from different types of applications.

- “JNDI lookup from an application running in a container”
- “JNDI lookup from an application that does not run in a container” on page 930
- “JNDI lookup with a corbaname URL” on page 932

### JNDI lookup from an application running in a container

Applications that run in a container can use `java:` lookup names. Lookup names of this form provide a level of indirection such that the lookup name used to look up an object is not dependent on the object's name as it is bound in the name server's namespace. The deployment descriptors for the application

provide the mapping from the java: name and the name server lookup name. The container sets up the java: namespace based on the deployment descriptor information so that the java: name is correctly mapped to the corresponding object.

The following example shows a lookup of an EJB 3.0 remote business interface. The actual home lookup name is determined by the interface's ibm-ejb-jar-bnd.xml binding file, if present, or by the default name assigned by the EJB container if no binding file is present. For more information, see topics on default bindings for business interfaces and homes and on user-defined bindings for EJB business interfaces and homes.

```
// Get the initial context as shown in a previous example.
...
// Look up the business interface using the JNDI name.
try {
   java.lang.Object ejbBusIntf =
      initialContext.lookup(
         "java:comp/env/com/mycompany/accounting/Account");
   accountIntf =
      (Account)javax.rmi.PortableRemoteObject.narrow(ejbBusIntf, Account.class);
}
   catch (NamingException e) { // Error getting the business interface
   ...
}
```

The following example shows a lookup of an EJB 1.x or 2.x EJB home. The actual home lookup name is determined by the application's deployment descriptors. The enterprise bean (EJB) resides in an EJB container, which provides an interface between the bean and the application server on which it resides.

```
// Get the initial context as shown in a previous example
...
// Look up the home interface using the JNDI name
try {
   java.lang.Object ejbHome =
      initialContext.lookup(
         "java:comp/env/com/mycompany/accounting/AccountEJB");
   accountHome = (AccountHome)javax.rmi.PortableRemoteObject.narrow(
      (org.omg.CORBA.Object) ejbHome, AccountHome.class);
}
   catch (NamingException e) { // Error getting the home interface
   ...
}
```

## JNDI lookup from an application that does not run in a container

Applications that do not run in a container cannot use java: lookup names because it is the container which sets the java: namespace up for the application. Instead, an application of this type must look the object up directly from the name server. Each application server contains a name server. System artifacts such as EJB homes are bound relative to the server root context in that name server. The various name servers are federated by means of a system namespace structure. The recommended way to look up objects on different servers is to qualify the name so that the name resolves from any initial context in the cell. If a relative name is used, the initial context must be the same server root context as the one under which the object is bound. The form of the qualified name depends on whether the qualified name is a topology-based name or a fixed name. Examples of each form of qualified name follow.

- **Topology-based qualified names**

  Topology-based qualified names traverse through the system namespace to the server root context under which the target object is bound. A topology-based qualified name resolves from any initial context in the cell.

  **Single server**

  The following example shows a lookup of an EJB business interface that is running in the single server, MyServer, configured in the node, Node1.

```
// Get the initial context as shown in a previous example.
// Using the form of lookup name below, it does not matter which
// server in the cell is used to obtain the initial context.
...
// Look up the business interface using the JNDI name
try {
   java.lang.Object ejbBusIntf = initialContext.lookup(
      "cell/nodes/Node1/servers/MyServer/com/mycompany/accounting/Account");
   accountIntf =
     (Account)javax.rmi.PortableRemoteObject.narrow(ejbBusIntf, Account.class);
}
catch (NamingException e) { // Error getting the business interface
   ...
}
```

The following example shows a lookup of an EJB home that is running in the single server, MyServer, configured in the node, Node1.

```
// Get the initial context as shown in a previous example
// Using the form of lookup name below, it doesn't matter which
// server in the cell is used to obtain the initial context.
...
// Look up the home interface using the JNDI name
try {
   java.lang.Object ejbHome = initialContext.lookup(
      "cell/nodes/Node1/servers/MyServer/com/mycompany/accounting/AccountEJB");
   accountHome = (AccountHome)javax.rmi.PortableRemoteObject.narrow(
      (org.omg.CORBA.Object) ejbHome, AccountHome.class);
}
catch (NamingException e) { // Error getting the home interface
   ...
}
```

- **Fixed qualified names**

  If the target object has a cell-scoped fixed name defined for it, you can use its qualified form instead of the topology-based qualified name. Even though the topology-based name works, the fixed name does not change with the specific cell topology or with the movement of the target object to a different server.

  An example lookup of an EJB business interface with a qualified fixed name follows.

```
// Get the initial context as shown in a previous example.
// Using the form of lookup name below, it does not matter which
// server in the cell is used to obtain the initial context.
...
// Look up the business interface using the JNDI name
try {
   java.lang.Object ejbBusIntf = initialContext.lookup(
     "cell/persistent/com/mycompany/accounting/Account");
   accountIntf =
     (Account)javax.rmi.PortableRemoteObject.narrow(ejbBusIntf, Account.class);
   }
catch (NamingException e) { // Error getting the business interface
...

}
```

  An example lookup with a qualified fixed name is shown below.

```
// Get the initial context as shown in a previous example
// Using the form of lookup name below, it doesn't matter which
// server in the cell is used to obtain the initial context.
...
// Look up the home interface using the JNDI name
try {
   java.lang.Object ejbHome = initialContext.lookup(
     "cell/persistent/com/mycompany/accounting/AccountEJB");
   accountHome = (AccountHome)javax.rmi.PortableRemoteObject.narrow(
      (org.omg.CORBA.Object) ejbHome, AccountHome.class);
```

```
    }
  catch (NamingException e) { // Error getting the home interface
  ...
  }
```

### JNDI lookup with a corbaname URL

A corbaname can be useful at times as a lookup name. If, for example, the target object is not a member of the federated namespace and cannot be located with a qualifiied name, a corbaname can be a convenient way to look up the object.

A lookup of an EJB business interface with a corbaname URL follows.

```
// Get the initial context as shown in a previous example.
...
// Look up the business interface using a corbaname URL.
try {
   java.lang.Object ejbBusIntf = initialContext.lookup(
      "corbaname:iiop:someHost:2809#com/mycompany/accounting/Account");
   accountIntf =
     (Account)javax.rmi.PortableRemoteObject.narrow(ejbBusIntf, Account.class);
}
catch (NamingException e) { // Error getting the business interface
   ...
}
```

A lookup with a corbaname URL follows.

```
// Get the initial context as shown in a previous example
...
// Look up the home interface using a corbaname URL
try {
   java.lang.Object ejbHome = initialContext.lookup(
      "corbaname:iiop:someHost:2809#com/mycompany/accounting/AccountEJB");
   accountHome = (AccountHome)javax.rmi.PortableRemoteObject.narrow(
      (org.omg.CORBA.Object) ejbHome, AccountHome.class);
}
catch (NamingException e) { // Error getting the home interface
   ...
}
```

## JNDI interoperability considerations

You must take extra steps to enable your programs to interoperate with non-product JNDI clients and to bind resources from MQSeries to a namespace.

### EJB clients running in an environment other than WebSphere Application Server accessing EJB applications running on WebSphere Application Server servers

When an enterprise bean (EJB) application running in WebSphere Application Server is accessed by a non-product EJB client, the JNDI initial context factory is presumed to be a non-product implementation. In this case, the default initial context is the cell root. If the JNDI service provider being used supports CORBA object URLs, the corbaname format can be used to look up the EJB home.

**Single server**

Following is a URL that has the bootstrap host **myHost**, the port **2809**, and the enterprise bean installed in the server **server1** in node **node1** and bound in that server under the name **myEJB**:

```
initialContext.lookup(
  "corbaname:iiop:myHost:2809#cell/nodes/node1/servers/server1/myEJB");
```

**Without CORBA object URL support**

If the JNDI initial context factory being used does not support CORBA object URLs, the initial context can be obtained from the server, and the lookup can be performed on the initial context as follows:

```
Hashtable env = new Hashtable();
env.put(CONTEXT.PROVIDER_URL, "iiop://myHost:2809");
Context ic = new InitialContext(env);
Object o = ic.lookup("cell/clusters/myCluster/myEJB");
```

### Binding resources from MQSeries 5.2

In releases previous to WebSphere Application Server Version 5.0, the MQSeries jmsadmin tool could be used to bind resources to the namespace. When used with a WebSphere Application Server namespace, the resource is bound within a transient partition in the namespace and does not persist past the life of the server process. Instead of binding the MQSeries resources with the jmsadmin tool, bind them from the administrative console, under **Resources** in the console navigation tree.

## JNDI caching

To increase the performance of Java Naming and Directory Interface (JNDI) operations, the product JNDI implementation employs caching to reduce the number of remote calls to the name server for lookup operations. For most cases, use the default cache setting.

When an InitialContext object is instantiated, an association is established between the InitialContext instance and a cache. The initial context and any contexts returned directly or indirectly from a lookup on the initial context are all associated with that same cache instance. By default, the association is based on the provider URL, in particular, the host name and port. The caller can specify the cache name to override this default behavior. A cache instance of a given name is shared by all instances of InitialContext configured to use a cache of that name which were created with the same context class loader in effect. Two enterprise bean (EJB) applications running in the same server will use their own cache instances, if they are using different context class loaders, even if the cache names are the same.

After an association between an InitialContext instance and cache is established, the association does not change. A `javax.naming.Context` object returned from a lookup operation inherits the cache association of the Context object on which the lookup was performed. Changing cache property values with the `Context.addToEnvironment()` or `Context.removeFromEnvironment()` method does not affect cache behavior. You can change properties affecting a given cache instance with each InitialContext instantiation.

A cache is restricted to a process and does not persist past the life of that process. A cached object is returned from lookup operations until either the maximum cache life for the cache is reached, or the maximum entry life for the object's cache entry is reached. After this time, a lookup on the object causes the cache entry for the object to be refreshed. By default, caches and cache entries have unlimited lifetimes.

Usually, cached objects are relatively static entities, and objects becoming stale is not a problem. However, you can set timeout values on cache entries or on a cache so that cache contents are periodically refreshed.

If a bind or rebind operation is executed on an object, the change is not reflected in any caches other than the one associated with the context from which the bind or rebind was issued. This scenario is most likely to happen when multiple processes are involved, since different processes do not share the same cache, and context objects in all threads in a process typically share the same cache instance for a given name service provider.

## JNDI cache settings

Various Java Naming and Directory Interface (JNDI) cache property settings follow. Ensure that all property values are string values.

### com.ibm.websphere.naming.jndicache.cachename

The name of the cache to associate with an initial context instance can be specified with this property.

It is possible to create multiple InitialContext instances, each operating on the namespace of a different name server. By default, objects from each bootstrap address are cached separately, since they each involve independent namespaces and name collisions could occur if they used the same cache. The provider URL specified when the initial context is created by default serves as the basis for the cache name. With this property, a JNDI client can specify a cache name. Valid options for cache names follow:

| Valid options | Resulting cache behavior |
|---|---|
| **providerURL (default)** | Use the value for java.naming.provider.url property as the basis for the cache name. Cache names are based on the bootstrap host and port specified in the URL. The boostrap host is normalized to a fully qualfied name, if possible. For example, "corbaname:iiop:server1:2809#some/starting/context" and "corbaloc:iiop://server1" are normalized to the same cache name. If no provider URL is specified, a default cache name is used. |
| **Any string** | Use the specified string as the cache name. You can use any arbitrary string with a value other than "providerURL" as a cache name. |

### com.ibm.websphere.naming.jndicache.cacheobject

Turn caching on or off and clear an existing cache with this property.

By default, when an InitialContext is instantiated, it is associated with an existing cache or, if one does not exist, a new one is created. An existing cache is used with its existing contents. In some circumstances, this behavior is not desirable. For example, when objects that are looked up change frequently, they can become stale in the cache. Other options are available. The following table lists these other options along with the corresponding property value.

| Valid values | Resulting cache behavior |
|---|---|
| **populated (default)** | Use a cache with the specified name. If the cache already exists, leave existing cache entries in the cache; otherwise, create a new cache. |
| **cleared** | Use a cache with the specified name. If the cache already exists, clear all cache entries from the cache; otherwise, create a new cache. |
| **none** | Do not cache. If this option is specified, the cache name is irrelevant. Therefore, this option will not disable a cache that is already associated with other InitialContext instances. The InitialContext that is instantiated is not associated with any cache. |

### com.ibm.websphere.naming.jndicache.maxcachelife

Impose a limit to the age of a cache with this property.

By default, cached objects remain in the cache for the life of the process or until cleared with the com.ibm.websphere.naming.jndicache.cacheobject property set to `cleared`. This property enables a JNDI client to set the maximum life of a cache. This property differs from the maxentrylife property (below) in that the entire cache is cleared when the cache lifetime is reached. The table below lists the various maxcachelife values and their affect on cache behavior:

| Valid values | Resulting cache behavior |
|---|---|
| **0 (default)** | Make the cache lifetime unlimited. |

| Valid values | Resulting cache behavior |
| --- | --- |
| **Positive integer** | Set the maximum lifetime of the entire cache, in minutes, to the specified value. When the maximum lifetime for the cache is reached, the next attempt to read any entry from the cache causes the cache to be cleared |

### com.ibm.websphere.naming.jndicache.maxentrylife

Impose a limit to the age of individual cache entries with this property.

By default, cached objects remain in the cache for the life of the process or until cleared with the com.ibm.websphere.naming.jndicache.cacheobject property set to `cleared`. This property enables a JNDI client to set the maximum lifetime of individual cache entries. This property differs from the maxcachelife property in that individual entries are refreshed individually as their maximum lifetime reached. This might avoid any noticeable change in performance that might occur if the whole cache is cleared at once. The table below lists the various maxentrylife values and their effect on cache behavior:

| Valid values | Resulting cache behavior |
| --- | --- |
| **0 (default)** | Lifetime of cache entries is unlimited. |
| **Positive integer** | Set the maximum lifetime of individual cache entries, in minutes, to the specified value. When the maximum lifetime for an entry is reached, the next attempt to read the entry from the cache causes the individual cache entry to refresh. |

## JNDI to CORBA name mapping considerations

WebSphere Application Server name servers are an implementation of the CORBA CosNaming interface. The product provides a Java Naming and Directory Interface (JNDI) implementation which you can use to access CosNaming name servers through the JNDI interface. Issues can exist when mapping JNDI name strings to and from CORBA names.

Each component in a CORBA name consists of an `id` and `kind` field, but a JNDI name component consists of no such fields. Each component in a JNDI name is atomic. Typical JNDI clients do not need to make a distinction between the `id` and `kind` fields of a name component, or know how JNDI name strings map to CORBA names. JNDI clients of this sort can use the JNDI syntax described below. When a name is parsed according to JNDI syntax, each name component is mapped to the `id` field of the corresponding CORBA name component. The `kind` field always has an empty value. This basic syntax is the least obtrusive to the JNDI client in that it has the fewest special characters. However, you cannot represent with this syntax a CORBA name with a non-empty `kind` field. This restriction can prevent EJB applications from interoperating with CORBA applications.

Some clients, however must interoperate with CORBA applications which use CORBA names with non-empty `kind` fields. These JNDI clients must make a distinction between `id` and `kind` so that JNDI names are correctly mapped to CORBA names, particularly when the CORBA names contain components with non-empty `kind` fields. Such JNDI clients can use the INS name syntax. With its additional special character, you can use INS to represent any CORBA name. Use of this syntax is not recommended unless it is necessary, because this syntax is more restrictive from the JNDI client's perspective in that the JNDI client must be aware that name components with multiple unescaped dots are syntactically invalid. INS name syntax is part of the OMG CosNaming Interoperable Naming Specification.

# Developing applications that use CosNaming (CORBA Naming interface)

CORBA clients can perform naming operations on WebSphere Application Server name servers through the CosNaming interface.

## About this task

The following examples show how to obtain an ORB instance and an initial context as well as how to look up an EJB home.

## Procedure

1. Get an initial context.
2. Perform desired CosNaming operations.

# Example: Getting an initial context with CosNaming

In WebSphere Application Server, an initial context is obtained from a bootstrap server. The address for the bootstrap server consists of a host and port. To get an initial context, you must know the host and port for the server that is used as the bootstrap server.

Obtaining an initial context consists of two basic steps:
1. Obtain an ORB reference.
2. Use an ORB reference to get an initial context. Alternatively, use an existing ORB and invoke string_to_object with a CORBA object URL with multiple name server addresses to get an initial context.

## Obtaining an ORB reference

Pure CosNaming clients, that is clients that are not running in a server process, must create and initialize an ORB instance with which to obtain the initial context. CosNaming clients which run in server processes can obtain a reference to the server ORB with a JNDI lookup. The following examples illustrate how to create and initialize a client ORB and how to obtain a server ORB reference.

### Creating a client ORB instance

To create an ORB instance, invoke the static method, org.omg.CORBA.ORB.init. The init method requires a property set to the name of the ORB class you want to instantiate. An ORB implementation with the class name com.ibm.CORBA.iiop.ORB is included with the product. The WebSphere Application Server ORB recognizes additional properties with which you can specify initial references.

The basic steps for creating an ORB are as follows:
1. Create a Properties object.
2. Set the ORB class property to the product's ORB class.
3. Set the initial reference properties.
4. Invoke ORB.init, passing in the Properties object.

AIX HP-UX Linux Solaris Windows

```
...
import java.util.Properties;
import org.omg.CORBA.ORB;
...
Properties props = new Properties();
props.put("org.omg.CORBA.ORBClass", "com.ibm.CORBA.iiop.ORB");
props.put("com.ibm.CORBA.ORBInitRef.NameService",
      "corbaloc:iiop:myhost.mycompany.com:2809/NameService");
props.put("com.ibm.CORBA.ORBInitRef.NameServiceServerRoot",
      "corbaloc:iiop:myhost.mycompany.com:2809/NameServiceServerRoot");
ORB _orb = ORB.init((String[])null, props);
...
```

### Obtaining a reference to the server ORB

CosNaming clients which run in a server process can obtain a reference to the server ORB with a JNDI lookup on a java: name, shown as follows:

```
...
import javax.naming.Context;
import javax.naming.InitialContext;
import org.omg.CORBA.ORB;
...
Context initialContext = new InitialContext();
ORB orb = (ORB) initialContext.lookup("java:comp/ORB");
...
```

## Using an ORB reference to get an initial naming reference

There are two basic ways to get an initial CosNaming context. Both ways involve an ORB method invocation. The first way is to invoke the resolve_initial_references method on the ORB with an initial reference key. For this call to work, the ORB must be initialized with an initial reference for that key. The other way is to invoke the string_to_object method on the ORB, passing in a CORBA object URL with the host and port of the bootstrap server. The following examples illustrate both approaches.

### Invoking resolve_initial_references

Once an ORB reference is obtained, invoke the resolve_initial_references method on the ORB to obtain a reference to the initial context. The following code example invokes resolve_initial_reference on an ORB reference.

```
...
import org.omg.CORBA.ORB;
import org.omg.CosNaming.NamingContextExt;
import org.omg.CosNaming.NamingContextExtHelper;
...
// Obtain ORB reference as shown in examples earlier in this section
...
org.omg.CORBA.Object obj = _orb.resolve_initial_references("NameService");
NamingContextExt initCtx = NamingContextExtHelper.narrow(obj);
...
```

Note that the key NameService is passed to the resolve_initial_references method. Other initial context keys are registered in product servers. For example, NameServiceServerRoot can be used to obtain a reference to the server root context in the bootstrap name server. For more information on the initial contexts registered in server ORBs, refer to the topic on initial context support.

### Invoking string_to_object with a CORBA object URL

You can use an INS-compliant ORB to obtain an initial context even if the ORB is not initialized with any initial references or bootstrap properties, or if those property settings are for a different server than the name server from which you want to obtain the initial context. To obtain an initial context by explicitly specifying the bootstrap name server, invoke the string_to_object method on the ORB, passing in a CORBA object URL which contains the bootstrap server host and port.

The code in the example below invokes the string_to_object method on an existing ORB reference, passing in a CORBA object URL which identifies the desired initial context.

```
...
import org.omg.CORBA.ORB;
import org.omg.CosNaming.NamingContextExt;
import org.omg.CosNaming.NamingContextExtHelper;
...
// Obtain ORB reference as shown in examples earlier in this section
...
org.omg.CORBA.Object obj =
 orb.string_to_object("corbaloc:iiop:myhost.mycompany.com:2809/NameService");
NamingContextExt initCtx = NamingContextExtHelper.narrow(obj);
...
```

Note that the key NameService is used in the corbaloc URL. Other initial context keys are registered in product servers. For example, you can use NameServiceServerRoot to obtain a reference to the server root context in the bootstrap name server.

### Using an existing ORB and invoking string_to_object with a CORBA object URL with multiple name server addresses to get an initial context

CORBA object URLs can contain more than one bootstrap server address. Use this feature when attempting to obtain an initial context from a server cluster. You can specify the bootstrap server addresses for all servers in the cluster in the URL. The operation will succeed if at least one of the servers is running, eliminating a single point of failure. There is no guarantee of any particular order in which the address list will be processed. For example, the second bootstrap server address may be used to obtain the initial context even though the first bootstrap server in the list is available. An example of a corbaloc URL with multiple addresses follows.

```
...
import org.omg.CORBA.ORB;
import org.omg.CosNaming.NamingContextExt;
import org.omg.CosNaming.NamingContextExtHelper;
...
// Assume orb is an existing ORB instance
org.omg.CORBA.Object obj = orb.string_to_object(
   "corbaloc::myhost1:9810,:myhost1:9811,:myhost2:9810/NameService");
NamingContextExt initCtx = NamingContextExtHelper.narrow(obj);
...
```

## Example: Looking up an EJB home with CosNaming

You can look up an EJB home or other CORBA object from a WebSphere Application Server name server through the CORBA CosNaming interface.

You can invoke `resolve` or `resolve_str` on the initial context, or you can invoke `string_to_object` on the ORB. You can use a qualified name so that the name resolves regardless of which name server the lookup is executed on, or use an unqualified name that only resolves from the server root context on the name server that actually contains the object binding. (The qualified name traverses the federated system namespace to the specified server root context.)

### Qualified and unqualified names

Each application server contains a name server. System artifacts such as EJB homes are bound in that name server. The various name servers are federated by means of a system namespace structure. The recommended way to look up objects on different servers is to use a qualified name.

A qualified name can be a topology-based name, based on the name of the single server and node that contains the object.

You can define fixed qualified names for objects. With qualified names, you can look up objects residing on different servers from the same initial context by traversing the system namespace structure. Alternatively, you can use an unqualified name, but an unqualified name will only resolve using the name server associated with the object's application server.

### CosNaming.resolve (and resolve_str) vs. ORB.string_to_object

If you have an initial context from any name server in a WebSphere Application Server cell, you can look up any CORBA object with a qualified name. You do not need additional host and port information for the target object's name server.

Alternatively, you can look up an object by invoking `string_to_object` on the ORB, passing in a corbaname URL. Typically, an IIOP type URL is specified, so the bootstrap address information required

for an initial context must be contained in the URL. You can use a qualified or unqualified stringified name, but an unqualifed name resolves only if the initial context is from the name server in which the object is bound.

The following examples show CosNaming resolve operations using qualified topology-based lookup names and an unqualified lookup name.

## CosNaming resolve operation using a qualified name

The topology-based qualified name can be found for an object that is bound in a single server.

### Single server

The following example shows the lookup of an EJB home that is running in a single server. The enterprise bean that is being looked up is running in the server, `MyServer`, on the node, `Node1`.

```
// Get the initial context as shown in the previous example
// Using the form of lookup name below, it doesn't matter which
// server in the cell is used to obtain the initial context.
...
// Look up the home interface using the name under which the EJB home is bound
org.omg.CORBA.Object ejbHome = initialContext.resolve_str(
  "cell/nodes/Node1/servers/MyServer/mycompany/accounting/AccountEJB");
accountHome =
  (AccountHome)javax.rmi.PortableRemoteObject.narrow(ejbHome, AccountHome.class);
```

## ORB string_to_object operation using an unqualified stringified name

If the resolve operation is being performed on the name server that contains the object, the system namespace does not need to be traversed, and you can use an unqualified lookup name. Note that this name does not resolve on other name servers. If an unqualified name is provided, the object key must be NameServiceServerRoot so that the correct initial context is selected. If a qualified name is provided, you can use the default key of NameService.

The following example shows a lookup of an EJB home. The enterprise bean that is being looked up is bound on the name server running on the host `myHost` on port `2809`. Note the object key of `NameServiceServerRoot`.

```
// Assume orb is an existing ORB instance
...
// Look up the home interface using the name under which the EJB home is bound
org.omg.CORBA.Object ejbHome = orb.string_to_object(
    "corbaname:iiop:myHost:2809/NameServiceServerRoot#mycompany/accounting");
accountHome =
    (AccountHome)javax.rmi.PortableRemoteObject.narrow(ejbHome, AccountHome.class);
```

# Chapter 20. Developing Object pools

This page provides a starting point for finding information about object pools.

Object pools provide an effective means of improving application performance at run time, by supporting the reuse of multiple instances of objects.

## Using object pools

An object pool helps an application avoid creating new Java objects repeatedly. Most objects can be created once, used and then reused. An object pool supports the pooling of objects waiting to be reused.

### About this task

Object pools are not meant to be used for pooling JDBC connections or Java Message Service (JMS) connections and sessions. WebSphere Application Server provides specialized mechanisms for dealing with those types of objects. These object pools are intended for pooling application-defined objects or basic Developer Kit types.

To use an object pool, the product administrator must define an *object pool manager* using the administrative console. Multiple object pool managers can be created in an Application Server cell.

**Note:** The Object pool manager service is only supported from within the EJB container or Web container. Looking up and using a configured object pool manager from a Java 2 Platform Enterprise Edition (J2EE) application client container is not supported.

### Procedure

1. Start the administrative console.
2. Click **Resources > Object pool managers**.
3. Specify a **Scope** value and click **New**.
4. Specify the required properties for work manager settings.
   **Scope** The scope of the configured resource. This value indicates the location for the configuration file.
   **Name** The name of the object pool manager. This name can be up to 30 ASCII characters long.
   **JNDI Name**
   The Java Naming and Directory Interface (JNDI) name for the pool manager.
5. [Optional] Specify a **Description** and a **Category** for the object pool manager.

### Results

After you have completed these steps, applications can find the object pool manager by doing a JNDI lookup using the specified JNDI name.

### Example

The following code illustrates how an application can find an object pool manager object:

```
InitialContext ic = new InitialContext();
ObjectPoolManager opm = (ObjectPoolManager)ic.lookup("java:comp/env/pool");
```

When the application has an ObjectPoolManager, it can cache an object pool for classes of the types it wants to use. The following is an example:

```
ObjectPool arrayListPool = null;
ObjectPool vectorPool = null;
try
```

© Copyright IBM Corp. 2011

```
{
 arrayListPool = opm.getPool(ArrayList.class);
 vectorPool = opm.getPool(Vector.class);
}
catch(InstantiationException e)
{
 // problem creating pool
}
catch(IllegalAccessException e)
{
 // problem creating pool
}
```

When the application has the pools, the application can use them as in the following example:

```
ArrayList list = null;
try
{
 list = (ArrayList)arrayListPool.getObject();
 list.clear(); // just in case
 for(int i = 0; i < 10; ++i)
 {
  list.add("" + i);
 }
 // do what ever we need with the ArrayList
}
finally
{
 if(list != null) arrayListPool.returnObject(list);
}
```

This example presents the basic pattern for using object pooling. If the application does not return the object, then the only adverse effect is that the object cannot be reused.

## Object pool managers

Object pool managers control the reuse of application objects and Developer Kit objects, such as Vectors and HashMaps.

Multiple object pool managers can be created in an Application Server cell. Each object pool manager has a unique cell-wide Java Naming and Directory Interface (JNDI) name. Applications can find a specific object pool manager by doing a JNDI lookup using the specific JNDI name.

The object pool manager and its associated objects implement the following interfaces:

```
public interface ObjectPoolManager
{
 ObjectPool getPool(Class aClass)
  throws InstantiationException, IllegalAccessException;
 ObjectPool createFastPool(Class aClass)
  throws InstantiationException, IllegalAccessException;

}

public interface ObjectPool
{
 Object getObject();
 void returnObject(Object o);

}
```

The getObject() method removes the object from the object pool. If a getObject() call is made and the pool is empty, then an object of the same type is created. A returnObject( ) call puts the object back into the object pool. If returnObject() is not called, then the object is no longer allocatable from the object pool. If the object is not returned to the object pool, then it can be garbage collected.

Each object pool manager can be used to pool any Java object with the following characteristics:
- The object must be a public class with a public default constructor.
- If the object implements the java.util.Collection interface, it must support the optional clear() method.

Each pooled object class must have its own object pool. In addition, an application gets an object pool for a specific object using either the ObjectPoolManager.getPool() method or the ObjectPoolManager.createFastPool() method. The difference between these methods is that the getPool() method returns a pool that can be shared across multiple threads. The createFastPool() method returns a pool that can only be used by a single thread.

If in a Java virtual machine (JVM), the getPool() method is called multiple times for a single class, the same pool is returned. A new pool is returned for each call when the createFastPool() method is called. Basically, the getPool() method returns a pool that is thread-synchronized.

The pool for use by multiple threads is slightly slower than a fast pool because of the need to handle thread synchronization. However, extreme care must be taken when using a fast pool.

Consider the following interface:

```
public interface PoolableObject
{
 void init();
 void returned();
}
```

If the objects placed in the pool implement this interface and the ObjectPool.getObject() method is called, the object that the pool distributes has the init() method called on it. When the ObjectPool.returnObject() method is called, the PoolableObject.returned() method is called on the object before it is returned to the object pool. Using this method objects can be pre-initialized or cleaned up.

It is not always possible for an object to implement PoolableObject. For example, an application might want to pool ArrayList objects. The ArrayList object needs clearing each time the application reuses it. The application might extend the ArrayList object and have the ArrayList object implement a poolable object. For example, consider the following:

```
public class PooledArrayList extends ArrayList implements PoolableObject
{
 public PooledArrayList()
 {
 }

 public void init() {
 }

 public void returned()
 {
  clear();
 }
}
```

If the application uses this object, in place of a true ArrayList object, the ArrayList object is cleared automatically when it is returned to the pool.

Clearing an ArrayList object simply marks it as empty and the array backing the ArrayList object is not freed. Therefore, as the application reuses the ArrayList, the backing array expands until it is big enough for all of the application requirements. When this point is reached, the application stops allocating and copying new backing arrays and achieves the best performance.

It might not be possible or desirable to use the previous procedure. An alternative is to implement a custom object pool and register this pool with the object pool manager as the pool to use for classes of

that type. The class is registered by the WebSphere administrator when the object pool manager is defined in the cell. Take care that these classes are packaged in Java Archive (JAR) files available on all of the nodes in the cell where they might be used.

## Object pool managers collection

An object pool manages a pool of arbitrary objects and helps applications avoid creating new Java objects repeatedly. Most objects can be created once, used and then reused. An object pool supports the pooling of objects waiting to be reused. These object pools are not meant to be used for pooling Java Database Connectivity connections or Java Message Service (JMS) connections and sessions. WebSphere Application Server provides specialized mechanisms for dealing with those types of objects. These object pools are intended for pooling application-defined objects or basic Developer Kit types.

To view this administrative console page, click **Resources > Object pool managers**.

To use an object pool, the product administrator must define an object pool manager using the administrative console. Multiple object pool managers can be created in an Application Server cell.

### Name

Specifies the name by which the object pool manager is known for administrative purposes.

| | |
|---|---|
| **Data type** | String |
| **Range** | 1 through 30 ASCII characters |

### JNDI name

Specifies the Java Naming and Directory Interface (JNDI) name for the object pool manager.

| | |
|---|---|
| **Data type** | String |

### Scope

Specifies the scope of the configured resource. This value indicates the location for the configuration file.

### Description

Specifies the description of the object pool manager.

| | |
|---|---|
| **Data type** | String |

### Category

Specifies the category name used to classify or group this object pool manager.

| | |
|---|---|
| **Data type** | String |

## Object pool managers settings

An object pool manages a pool of arbitrary objects and helps applications avoid creating new Java objects repeatedly. Most objects can be created once, used and then reused. An object pool supports the pooling of objects waiting to be reused. These object pools are not meant to be used for pooling Java Database Connectivity connections or Java Message Service (JMS) connections and sessions. WebSphere Application Server provides specialized mechanisms for dealing with those types of objects. These object pools are intended for pooling application-defined objects or basic Developer Kit types.

To view this administrative console page, click **Resources > Object pool managers >** *objectpoolmanager_name*

To use an object pool, the product administrator must define an object pool manager using the administrative console. Multiple object pool managers can be created in an Application Server cell.

***Scope:***

Specifies the scope of the configured resource. This value indicates the location for the configuration file.

***Name:***

The name by which the object pool manager is known for administrative purposes.

| | |
|---|---|
| **Data type** | String |
| **Range** | 1 through 30 ASCII characters |

***JNDI Name:***

The Java Naming and Directory Interface (JNDI) name for the object pool manager.

| | |
|---|---|
| **Data type** | String |

***Description:***

A description of the object pool manager.

| | |
|---|---|
| **Data type** | String |

***Category:***

A category name used to classify or to group this object pool manager.

| | |
|---|---|
| **Data type** | String |

***Custom object pool collection:***

An object pool manages a pool of arbitrary objects and helps applications avoid creating new Java objects repeatedly. Most objects can be created once, used and then reused. An object pool supports the pooling of objects waiting to be reused. These object pools are not meant to be used for pooling Java Database Connectivity connections or Java Message Service (JMS) connections and sessions. WebSphere Application Server provides specialized mechanisms for dealing with those types of objects. These object pools are intended for pooling application-defined objects or basic Developer Kit types.

To view this administrative console page, click **Resources > Object pool managers >** *objectpoolmanager_name* **> Custom object pools**.

Use custom object pools to insert additional logic around the following mechanisms:

- Constructing an object pool (A list of properties can be set)
- Flushing the object pool
- Getting objects from the pool
- Returning objects from the pool

These features allow for actions such as, clearing the state of an object when returning it to the pool, configuring the state of an object when retrieving it from the pool, or configuring generic pools and sending instructions on how to behave using custom properties.

To use an object pool the product administrator must define an object pool manager using the administrative console. You can create multiple object pool managers in an Application Server cell.

*Pool class name:*

Specifies the fully qualified class name of the objects that are stored in the custom object pool.

**Data type** String

*Pool implementation class name:*

Specifies the fully qualified class name of the implementation class for the custom object pool.

**Data type** String

*Custom object pool settings:*

An object pool manages a pool of arbitrary objects and helps applications avoid creating new Java objects repeatedly. Most objects can be created once, used and then reused. An object pool supports the pooling of objects waiting to be reused. These object pools are not meant to be used for pooling Java Database Connectivity connections or Java Message Service (JMS) connections and sessions. WebSphere Application Server provides specialized mechanisms for dealing with those types of objects. These object pools are intended for pooling application-defined objects or basic Developer Kit types.

To view this administrative console page, click **Resources > Object pool managers >** *objectpoolmanager_name* **> Custom object pools >** *objectpool_name*.

Use custom object pools to insert additional logic around the following mechanisms:

- Constructing an object pool (A list of properties can be set)
- Flushing the object pool
- Getting objects from the pool
- Returning objects from the pool

These features allow for actions such as, clearing the state of an object when returning it to the pool, configuring the state of an object when retrieving it from the pool, or configuring generic pools and sending instructions on how to behave using custom properties.

To use an object pool, the product administrator must define an object pool manager using the administrative console. Multiple object pool managers can be created in an Application Server cell.

*Pool Class Name:*

The fully qualified class name of the objects that are stored in the object pool.

**Data type** String

*Pool Impl Class Name:*

The fully qualified class name of the CustomObjectPool implementation class for this object pool.

**Data type** String

## Object pool service settings

Use this page to enable or disable the object pool service, which manages object pool resources used by the server.

To view this administrative console page, click **Servers > Server Types > WebSphere application servers >** *server_name* > Container Services > **Object pool service**.

### Enable service at server startup

Specifies whether the server attempts to start the object pool service.

**Default**
Cleared

**Range**

**Selected**
When the application server starts, it attempts to start the object pool service automatically.

**Cleared**
The server does not try to start the object pool service. If object pool resources are used on this server, then the system administrator must start the object pool service manually or select this property, and then restart the server.

## Object pools: Resources for learning

This topic provides links to find relevant supplemental information about object pools.

Use the following links to find relevant supplemental information about object pools. The information resides on IBM and non-IBM Internet sites, whose sponsors control the technical accuracy of the information.

These links are provided for convenience. Often, the information is not specific to the IBM WebSphere Application Server product, but is useful all or in part for understanding the product. When possible, links are provided to technical papers and Redbooks that supplement the broad coverage of the release documentation with in-depth examinations of particular product areas.

Furthermore, these links provide guidance on using object pools. Since object pooling is a general topic and the WebSphere Application Server product implementation is only one way to use it, you must understand when object pooling is necessary. These articles help you make that decision.

### Programming model and decisions

- Build your own ObjectPool in Java to boost application speed
- Improve the robustness and performance of your ObjectPool
- Recycle broken objects in resource pools

## MBeans for object pool managers and object pools

Legacy MBean names for object pool managers and object pools are deprecated. The legacy names are based on the object pool manager name (which is not required to be unique) rather than the object pool manager JNDI name.

### About this task

For object pools, the legacy name is also lacking any identifier of the version of the pooled class. Additionally, object pool Performance Monitoring Instrumentation (PMI) statistics are aggregated for object pools with the same legacy object pool MBean name.

For example, if the object pool manager and pooled class are as follows:

```
object pool manager name:               My ObjectPool
object pool manager JNDI name:          op/MyObjectPool
pooled class name:                      java.util.ArrayList
hash code of java.util.ArrayList.class: 1111eb3f (hexadecimal)
```

the legacy object pool manager MBean name will be:

```
ObjectPoolManager_My ObjectPool
```

and the legacy object pool MBean name will be:

```
ObjectPool_My ObjectPool_java.util.ArrayList
```

Instead of using the deprecated legacy MBean names, use the MBean names that are based on the JNDI name of the object pool manager.

For the example above, the JNDI name-based object pool manager MBean name is:

```
ObjectPoolManager_op/MyObjectPool
```

and the JNDI name-based object pool MBean name is:

```
ObjectPool_op/MyObjectPool_java.util.ArrayList.class@1111eb3f
```

**Formats for MBean names**

| Type | Name format |
|---|---|
| Deprecated legacy object pool manager MBean name: | ObjectPoolManager_[object pool manager name] |
| JNDI name-based object pool manager MBean name: | ObjectPoolManager_[object pool manager JNDI name] |
| Deprecated legacy object pool MBean name: | ObjectPool_[object pool manager name]_[pooled class name] |
| JNDI name-based object pool MBean name: | ObjectPool_[object pool manager JNDI name]_[pooled class name].class@[hexadecimal representation of the hash code of the pooled class' java.lang.Class reference] |

In all of the above formats, characters that are not valid for MBean names are replaced with the '.' character.

# Chapter 21. Developing Object Request Broker (ORB)

This page provides a starting point for finding information about the Object Request Broker (ORB). The product uses an ORB to manage communication between client applications and server applications as well as among product components. These Java Platform, Enterprise Edition (Java EE) standard services are relevant to the ORB: Remote Method Invocation/Internet Inter-ORB Protocol (RMI/IIOP) and Java Interface Definition Language (Java IDL).

The ORB provides a framework for clients to locate objects in the network and call operations on those objects as though the remote objects were located in the same running process as the client, providing location transparency.

## Developing Object Request Brokers

## Client-side programming tips for the Object Request Broker service

Every Internet InterORB Protocol (IIOP) request and response exchange consists of a client-side ORB and a server-side ORB. It is important that any application that uses IIOP is properly programmed to communicate with the client-side Object Request Broker (ORB).

The following tips should help you ensure that an application that uses IIOP to handle request and response exchanges is properly programmed to communicate with the client-side Object Request Broker (ORB).

### Resolution of initial references to services

Client applications can use the ORBInitRef and ORBDefaultInitRef properties to configure the network location that the ORB service uses to find a service such as naming. When set, these properties are included in the parameters that are used to initialize the ORB, as illustrated in the following example:

```
org.omg.CORBA.ORB.init(java.lang.String[] args,
                       java.util.Properties props)
```

You can set these properties in client code or by command-line argument. It is possible to specify more than one service location by using multiple ORBInitRef property settings (one for each service), but only a single ORBDefaultInitRef value can be specified.

For setting in client code, these properties are com.ibm.CORBA.ORBInitRef.*service_name* and com.ibm.CORBA.ORBDefaultInitRef, respectively. For example, to specify that the naming service (NameService) is located in sample.server.com at port 2809, set the com.ibm.CORBA.ORBInitRef.NameService property to `corbaloc::sample.server.com:2809/NameService`.

For setting by command-line argument, these properties are -ORBInitRef and -ORBDefaultInitRef, respectively. To locate the same naming service specified previously, use the following Java command:

After these properties are set for services that the ORB supports, Java Platform, Enterprise Edition (Java EE) applications can call the resolve_initial_references function on the ORB, as defined in the CORBA/IIOP specification, to obtain the initial reference to a given service.

### Preferred API for obtaining an ORB instance

For Java EE applications, you can use either of the following approaches. However, it is strongly recommended that you use the Java Naming and Directory Interface (JNDI) approach to ensure that the same ORB instance is used throughout the client application; you avoid the unintended inconsistencies that might occur when different ORB instances are used.

© IBM Corporation 2009

**JNDI approach:** For Java EE applications (including enterprise beans, Java EE clients and servlets), you can obtain an ORB instance by creating a JNDI InitialContext object and looking up the ORB under the `java:comp/ORB` name, as illustrated in the following example:

```
javax.naming.Context ctx = new javax.naming.InitialContext();
org.omg.CORBA.ORB orb =
   (org.omg.CORBA.ORB)javax.rmi.PortableRemoteObject.narrow(ctx.lookup("java:comp/ORB"),
                                                            org.omg.CORBA.ORB.class);
```

The ORB instance obtained using JNDI is a singleton object, shared by all the Java EE components that are running in the same Java virtual machine process.

**Note:** You must use the JNDI approach if you want to take advantage of WLM functionality and cluster failover within the application. For information on how to obtain an InitialContext from a server cluster, see the example for using a CORBA object URL with multiple name server addresses, which is in the topic on getting an initial context by setting the provider URL property.

**CORBA approach:** Because thin-client applications do not run in a Java EE container, they cannot use JNDI interfaces to look up the ORB. In this case, you can obtain an ORB instance by using CORBA programming interfaces, as follows:

```
java.util.Properties props = new java.util.Properties();
java.lang.String[] args = new java.lang.String[0];
org.omg.CORBA.ORB orb = org.omg.CORBA.ORB.init(args, props);
```

In contrast to the JNDI approach, the CORBA specification requires that a new ORB instance be created each time the ORB.init method is called. If necessary to change the ORB default settings, you can add ORB property settings to the Properties object that is passed in the ORB.init method call.

The use of the com.ibm.ejs.oa.EJSORB.getORBinstance method, supported in previous releases of this product is deprecated.

## API restrictions with sharing an ORB instance among Java EE application components

For performance reasons, it often makes sense to share a single ORB instance among components in a Java EE application. As required by the Java EE Specification, Version 1.3, all web and EJB containers provide an ORB instance in the JNDI namespace as `java:comp/ORB`. Each container can share this instance among application components but is not required to. For proper isolation between application components, application code must comply with the following restrictions:

- Do not call the ORB shutdown or destroy methods
- Do not call org.omg.CORBA_2_3.ORB methods register_value_factory, or unregister_value_factory

In addition, do not share an ORB instance among application components in different Java EE applications.

## Required use of rmic and idlj that ship with the IBM Developer Kit

The Java Runtime Environment (JRE) used by this product includes the **rmic** and **idlj** tools. You use the tools to generate Java language bindings for the CORBA/IIOP protocol.

During product installation, the tools are installed in the *app_server_root*`/java/ibm_bin` directory. Versions of these tools included with Java development kits in the `$JAVA_HOME/bin` directory other than the IBM Developer Kit installed with this product are incompatible with this product.

When you install this product, the *app_server_root*`/java/ibm_bin` directory is included in the $PATH search order to enable use of the rmic and idlj scripts provided by IBM. Because the scripts are in the *app_server_root*`/java/ibm_bin` directory instead of the JRE standard *app_server_root*`/java/bin` directory, it is unlikely that you can overwrite them when applying maintenance to a JRE not provided by IBM.

In addition to the rmic and idlj tools, the JRE also includes Interface Definition Language (IDL) files. The files are based on those defined by the Object Management Group (OMG) and can be used by applications that need an IDL definition of selected ORB interfaces. The files are placed in the *app_server_root*/java/ibm_lib directory.

Before using either the rmic or idlj tool, ensure that the *app_server_root*/java/ibm_bin directory is included in the proper PATH variable search order in the environment. If your application uses IDL files in the *app_server_root*/java/ibm_lib directory, also ensure that the directory is included in the PATH variable.

# Directory conventions

References in product information to *app_server_root*, *profile_root*, and other directories imply specific default directory locations. This topic describes the conventions in use for WebSphere Application Server.

## Default product locations (distributed)

The following file paths are default locations. You can install the product and other components or create profiles in any directory where you have write access. Multiple installations of WebSphere Application Server - Express products or components require multiple locations. Default values for installation actions by root and nonroot users are given. If no nonroot values are specified, then the default directory values are applicable to both root and nonroot users.

*app_client_root*

*Table 125. Default installation root directories for the Application Client for IBM WebSphere Application Server.*

*This table shows the default installation root directories for the Application Client for IBM WebSphere Application Server.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/AppClient (Java EE Application client only)<br>HP-UX Linux Solaris /opt/IBM/WebSphere/AppClient (Java EE Application client only)<br>Windows C:\Program Files\IBM\WebSphere\AppClient |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/AppClient (Java EE Application client only)<br>Windows C:\IBM\WebSphere\AppClient |

*app_server_root*

*Table 126. Default installation directories for WebSphere Application Server.*

*This table shows the default installation directories for WebSphere Application Server - Express.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/AppServer<br>HP-UX Linux Solaris /opt/IBM/WebSphere/AppServer<br>Windows C:\Program Files\IBM\WebSphere\AppServer |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/AppServer<br>Windows *user_home*\IBM\WebSphere\AppServer |

*component_root*

The component installation root directory is any installation root directory described in this topic.

Some programs are for use across multiple components—in particular, the Web Server Plug-ins, the Application Client, and the IBM HTTP Server. All of these components are part of the product package.

*gskit_root*

IBM Global Security Kit (GSKit) can now be installed by any user. GSKit is installed locally inside the installing product's directory structure and is no longer installed in a global location on the target system. The following list shows the default installation root directory for Version 8 of the GSKit, where *product_root* is the root directory of the product that is installing GSKit, for example IBM HTTP Server or the web server plug-in.

AIX HP-UX Linux Solaris

*product_root*/gsk8

Windows

*product_root*\gsk8

*profile_root*

*Table 127. Default profile directories.*

# Chapter 22. Developing OSGi applications

You can develop bundles, optionally group them into composite bundles, and add them to an OSGi application or a bundle repository.

## Procedure

- Develop and deploy an OSGi application.

  As an introduction to developing an OSGi application, you can develop a simple hello-world OSGi application, which consists of two bundles. One bundle defines a hello service, and the other is a client bundle that uses this service to produce the message “OSGi Service: Hello World!”.
- Develop a composite bundle.

  A composite bundle groups shared bundles together into aggregates. It provides one or more packages at specific versions to an OSGi application. You can also extend a deployed application by adding one or more composite bundles to the composition unit for the application.
- Convert existing applications to OSGi applications.

  You can convert an enterprise application or a Spring application to an OSGi application.

## What to do next

You might also want to explore the sample OSGi applications.

# Developing and deploying an OSGi application

As an introduction to developing an OSGi application, you can develop a simple hello-world OSGi application, which consists of two bundles. One bundle defines a hello service, and the other is a client bundle that uses this service to produce the message “OSGi Service: Hello World!”.

## About this task

An OSGi application is a Java application that uses OSGi technologies. OSGi applications are collections of OSGi bundles (typically bundles that use the Blueprint component model), and can expose or consume a number of services. The OSGi application described in these topics demonstrates the use of the OSGi service registry to share the hello service between the defining bundle and the client bundle. All interactions with the service registry are handled through Blueprint.

OSGi bundles are packaged as Java archive (.jar) files. A single OSGi application is packaged in an enterprise bundle archive (.eba) file, just as an enterprise application is packaged in an enterprise archive (.ear) file. In this example application, the bundles are packaged directly in the .eba file. However the .eba file does not have to contain the bundles; they can be pulled in at run time.

**Note:** In the following procedure, the first three steps are specific to this example application, and lead you through creating the application artefacts using IBM Rational Application Developer Version 8 or similar tooling. The final step is not specific to this example application, and describes the process of deploying any OSGi application in WebSphere Application Server, using the administrative console or wsadmin commands.

## Procedure

1. Create your service bundle.
2. Create your client bundle.
3. Create your OSGi application.
4. Deploy an OSGi application as a business-level application.

© Copyright IBM Corp. 2011

### What to do next

To help solve any unexpected problems with your deployed applications, you can debug the bundles at run time using the command-line console.

You might also want to explore the sample OSGi applications.

## Creating a service bundle

For the simple hello-world OSGi application, the service bundle declares the HelloWorldEBA interface, and exports it as an OSGi service.

### About this task

A bundle, the modular unit in the OSGi model, is a JAR file that includes the OSGi application metadata. This metadata is defined in the manifest file of the JAR file, `META-INF/MANIFEST.MF`.

IBM Rational Application Developer Version 8 provides graphical support for creating and packaging bundles. The sample procedure below uses this tool. You can also use other tools, and the steps are adaptable to other tools.

This sample procedure builds a bundle called `com.ibm.ws.eba.helloWorldService`. This bundle declares the HelloWorldEBA interface, and exports it as an OSGi service. The exported service is used by client bundle `com.ibm.ws.eba.helloWorldClient`, as described in "Creating a client bundle" on page 958.

**Note:** In this simple example, the interface definition and implementation are co-located in the same bundle. In a more realistic business scenario, you would separate the service interface declaration and service implementation into separate bundles, because the interface declaration is likely to change far less often than the business implementation of the service.

### Procedure

1. Create an OSGi bundle project.
   a. Click **File** > **New** > **Project**. The Select a wizard panel is displayed.
   b. Click **OSGi** > **OSGi Bundle Project**, then click **Next**. The OSGi Bundle Project panel is displayed.
   c. Configure the project.
      - For **Project name**, enter `com.ibm.ws.eba.helloWorldService`.
      - Leave the other options as the default values.
   d. Click **Next**. The Java Configuration panel is displayed. Accept the default values for all the options on this panel.
   e. Click **Next**. The OSGi bundle settings panel is displayed. Accept the default values for all the options on this panel.
   f. Click **Finish**.

   You have created your OSGi project.
2. Declare and implement the `HelloWorld` service.
   a. Create a package called `com.ibm.ws.eba.helloWorld`, that includes an interface called `HelloWorldEBA`. Code this interface to contain just one method: hello().

      **Note:** In a later step, you create code in a Blueprint XML file that exposes this interface as a service.

      1) Under your `com.ibm.ws.eba.helloWorldService` project, right-click the folder `src`, then select **new** > **package**.
      2) Name the new package `com.ibm.ws.eba.helloWorld`.

3) Click **Finish**.
4) Right-click the new package, then select **new** > **interface**.
5) Name the new interface `HelloWorldEBA`.
6) Click **Finish**.
7) Copy and paste the following method to replace the content of the interface file:

```
package com.ibm.ws.eba.helloWorld;
public interface HelloWorldEBA {

    public void hello();
}
```

8) Save and close the file.

b. Create a package called `com.ibm.ws.eba.helloWorld.impl`, that includes an implementation class called `HelloWorldEBAImpl`. Code this class to implement the hello() method from the `HelloWorldEBA` interface. This implementation of the class causes "OSGi Service: Hello World!" to be displayed.
1) Under your `com.ibm.ws.eba.helloWorldService` project, right-click the folder `src`, then select **new** > **package**.
2) Name the new package `com.ibm.ws.eba.helloWorld.impl`.
3) Click **Finish**.
4) Right-click the new package, then select **new** > **class**.
5) Name the new interface implementation class `HelloWorldEBAImpl`.
6) Click **Finish**.
7) Copy and paste the following method to replace the content of the interface implementation class file:

```
package com.ibm.ws.eba.helloWorld.impl;

import com.ibm.ws.eba.helloWorld.HelloWorldEBA;

public class HelloWorldEBAImpl implements HelloWorldEBA {
    @Override
    public void hello() {
        System.out.println("OSGi Service: Hello World!");
    }
}
```

8) Save and close the file.

3. Create a Blueprint configuration.

A Blueprint configuration contains the bundle component assembly and configuration information. It also describes how components are registered in the OSGi service registry, or how they look up services from the OSGi service registry. This information is used at run time to instantiate and configure the required components when the bundle is started.

a. In the project `com.ibm.ws.eba.helloWorldService`, create a Blueprint XML file:
1) Click **File** > **New** > **Other** > **OSGi** > **Blueprint File**.
2) Accept the default values for all the options on this panel.
3) Click **Finish**.

b. Update the Blueprint XML file to contain the following Blueprint information:

```
<?xml version="1.0" encoding="UTF-8"?>
<blueprint xmlns="http://www.osgi.org/xmlns/blueprint/v1.0.0">
  <bean id="helloEBA" class="com.ibm.ws.eba.helloWorld.impl.HelloWorldEBAImpl"/>
  <service ref="helloEBA" interface="com.ibm.ws.eba.helloWorld.HelloWorldEBA"/>
</blueprint>
```

In the previous code block:

- The `bean` element defines a Blueprint component to be instantiated. In this example, the `bean` element causes bean `helloEBA` to be instantiated, by calling the constructor for the `com.ibm.ws.eba.helloWorld.impl.HelloWorldEBAImpl` class.

- The **id** attribute identifies the bean. You must specify this attribute if the bean is referenced from elsewhere in the Blueprint information, for example from the `service` element.
- The **class** attribute specifies which implementation class of the bean is instantiated.

- The `service` element defines the registration of a component in the OSGi service registry. In this example, the `service` element registers the bean with the name `helloEBA` as a service in the OSGi service registry with interface `com.ibm.ws.eba.helloWorld.HelloWorldEBA`, specified by the interface attribute.
  - The **ref** attribute refers to the **id** of the bean to be registered. This **id** is defined in the `bean` element.
  - The **interface** attribute refers to the interface that the bean class implements.

  For more information, see section 121.5 “Bean Manager” and section 121.6 “Service Manager” of the OSGi Service Platform Release 4 Version 4.2 Enterprise Specification.

**Note:** You might get an exception message (visible in the Problems pane) saying that there is no `bin.include` entry for `OSGI-INF` in the build properties file. If you see this message, use the **quick-fix** option to add the entry (right-click the problem, then select **quick-fix**).

4. Configure the `com.ibm.ws.eba.helloWorld` package as an exported package.

   Edit the bundle manifest to allow other bundles to load classes from the `com.ibm.ws.eba.helloWorld` package. Classes that are in packages not exported in the bundle manifest are private to the defining bundle and cannot be loaded by any other bundle.

   a. Open the bundle `MANIFEST.MF` file with the manifest editor. This file is in the `BundleContent/META-INF` directory.
   b. Click the **Runtime** tab.
   c. In the Exported Packages pane, click **Add**.
   d. Select the `com.ibm.ws.eba.helloWorld` package from the list, then click **OK**.
   e. In the Exported Packages pane, click **Properties**.
   f. In the **Properties** dialog, set the **version** to `1.0.0`, then click **OK**.
   g. Save the changes in the manifest editor. Click **File** > **Save**.

### Results

You have created a bundle called `com.ibm.ws.eba.helloWorldService`. This bundle contains the business logic and metadata needed to export the HelloWorldEBA service.

### What to do next

You can now create the client bundle that uses the HelloWorldEBA service.

## Creating a client bundle

For the simple hello-world OSGi application, the client bundle consumes the HelloWorldEBA service, and uses it to produce the message “OSGi Service: Hello World!”.

### Before you begin

This task assumes that you have already created the HelloWorldEBA service, as described in “Creating a service bundle” on page 956.

### About this task

A bundle, the modular unit in the OSGi model, is a JAR file that includes the OSGi application metadata. This metadata is defined in the manifest file of the JAR file, `META-INF/MANIFEST.MF`.

IBM Rational Application Developer Version 8 provides graphical support for creating and packaging bundles. The sample procedure below uses this tool. You can also use other tools, and the steps are adaptable to other tools.

This sample procedure builds a bundle called `com.ibm.ws.eba.helloWorldClient`. This bundle uses the HelloWorldEBA service that is exported by the bundle `com.ibm.ws.eba.helloWorldService`, as described in "Creating a service bundle" on page 956.

## Procedure

1. Create an OSGi bundle project.
   a. Click **File** > **New** > **Project**. The Select a wizard panel is displayed.
   b. Click **OSGi** > **OSGi Bundle Project**, then click **Next**. The OSGi Bundle Project panel is displayed.
   c. Configure the project.
      - For **Project name**, enter `com.ibm.ws.eba.helloWorldClient`.
      - Leave the other options as the default values.
   d. Click **Next**. The Java Configuration panel is displayed. Accept the default values for all the options on this panel.
   e. Click **Next**. The OSGi bundle settings panel is displayed. Accept the default values for all the options on this panel.
   f. Click **Finish**.

   You have created your OSGi project.
2. Make the HelloWorldEBA service available to the client bundle.

   Edit the client bundle manifest to make classes inside the `com.ibm.ws.eba.helloWorld` package available to the client bundle. The `com.ibm.ws.eba.helloWorld` package is part of the `com.ibm.ws.eba.helloWorldService` bundle.
   a. Open the bundle `MANIFEST.MF` file with the manifest editor. This file is in the `BundleContent/META-INF` directory.
   b. Click the **Dependencies** tab.
   c. In the Imported Packages pane, click **Add**.
   d. In the Package Selection dialog, enter `com.ibm.ws.eba.helloWorld` then click **OK**. The package is added to the Imported Packages list.
   e. In the Imported Packages list, select the `com.ibm.ws.eba.helloWorld` package then click **Properties**.
   f. In the **Properties** dialog, set the **minimum version** to `1.0.0 Inclusive`, and set the **maximum version** to `2.0.0 Exclusive`, then click **OK**. The entry for this package in the Imported Packages list is updated to `com.ibm.ws.eba.helloWorld [1.0.0,2.0.0)`.

      **Note:** This version syntax means "exported packages with versions between 1.0.0 inclusive and 2.0.0 exclusive will match this import". For more information, see section 3.2.6 "Version Ranges" of the OSGi Service Platform Release 4 Version 4.2 Core Specification.
   g. Save the changes in the manifest editor. Click **File** > **Save**.
3. Create a class `HelloWorldRefEBA`.
   a. In the project source folder `src`, create a package called `com.ibm.ws.eba.helloWorld.client`. In the package, create an interface called `HelloWorldRefEBA` with the following contents:

```
package com.ibm.ws.eba.helloWorld.client;

import com.ibm.ws.eba.helloWorld.HelloWorldEBA;

public interface HelloWorldRefEBA {
```

```
    public void refHello();
    public HelloWorldEBA getHelloWorldEBAService(); //property getter

}
```

b. In the same package, to implement the `HelloWorldRefEBA` interface, create a class called `HelloWorldRefEBAImpl` with the following contents:

```
package com.ibm.ws.eba.helloWorld.client;

import com.ibm.ws.eba.helloWorld.HelloWorldEBA;

public class HelloWorldRefEBAImpl implements HelloWorldRefEBA {
    private HelloWorldEBA helloWorldEBAService = null; //a reference to the service

    public void refHello() {
        System.out.println("Client: Start...");
        helloWorldEBAService.hello();
        System.out.println("Client: End...");
    }

    public HelloWorldEBA getHelloWorldEBAService() {
        return helloWorldEBAService;
    }

    public void setHelloWorldEBAService(HelloWorldEBA helloWorldEBAService) {
        this.helloWorldEBAService = helloWorldEBAService;
    }
}
```

In the previous code block:

- The line `HelloWorldEBA helloWorldEBAService = null;` defines the service dependency (the HelloWorldRefEBAImpl class depends on a service with a `HelloWorldEBA` interface).
- The line `helloWorldEBAService.hello();` demonstrates that a service has been injected for the `helloWorldEBAService` dependency.

4. Create a Blueprint configuration.

   A Blueprint configuration contains the bundle component assembly and configuration information. It also describes how components are registered in the OSGi service registry, or how they look up services from the OSGi service registry. This information is used at run time to instantiate and configure the required components when the bundle is started.

   a. In the project `com.ibm.ws.eba.helloWorldClient`, create a Blueprint XML file:

      1) Click **File** > **New** > **Other** > **OSGi** > **Blueprint File**.
      2) (Optional) Specify the file name. This can be any name provided it is an XML file. For example, `helloWorldRef.xml`.
      3) Leave the other options as the default values.
      4) Click **Finish**.

   b. Update the Blueprint XML file to contain the following Blueprint information. This Blueprint file specifies the internal wiring of the components.

```
<?xml version="1.0" encoding="UTF-8"?>
<blueprint xmlns="http://www.osgi.org/xmlns/blueprint/v1.0.0">
  <bean class="com.ibm.ws.eba.helloWorld.client.HelloWorldRefEBAImpl" init-method="refHello">
  <property name="helloWorldEBAService" ref="helloEBARef"/>
  </bean>
  <reference id="helloEBARef" interface="com.ibm.ws.eba.helloWorld.HelloWorldEBA"/>
</blueprint>
```

   In the previous code block:

   - The `init-method refHello` is called when the `com.ibm.ws.eba.helloWorld.client.HelloWorldRefEBAImpl` bean is created.
   - The `property` element specifies how a dependency is injected.

  - The property `helloWorldEBAService` is set by invoking the property setter `public void setHelloWorldEBAService(HelloWorldEBA helloWorldEBAService)`. You can use setter injection for bean properties that are defined in accordance with Java bean conventions.
  - The attribute `ref` specifies the Blueprint element ID of the component to be injected. The `ref` attribute must match a top-level element in this file. In this case, it matches the `reference` element.
- The `reference` element defines a dependency of this Blueprint module on an OSGi service with interface `com.ibm.ws.eba.helloWorld.HelloWorldRefEBA`. When the Blueprint Container starts this module, it must match the name of the interface attribute with an available service in the OSGi service registry. If this cannot be done, the Blueprint module is not started. In this case, the service is defined in the service element of the Blueprint XML of the service bundle.

For more information, see section 121.5 “Bean Manager” and section 121.7 “Service Reference Managers” of the OSGi Service Platform Release 4 Version 4.2 Enterprise Specification.

### Results

You have created a bundle called `com.ibm.ws.eba.helloWorldClient`. This bundle consumes the HelloWorldEBA service, and uses it to produce the message “OSGi Service: Hello World!”.

### What to do next

You can now create an OSGi application, in which multiple bundles are packaged together.

## Creating an OSGi application

For the simple hello-world OSGi application, the bundle that defines the service, and the bundle that uses the service, are packaged together in an OSGi application.

### Before you begin

This topic assumes that you have already completed the following tasks:

- “Creating a service bundle” on page 956 `com.ibm.ws.eba.helloWorldService`.
- “Creating a client bundle” on page 958 `com.ibm.ws.eba.helloWorldClient`.

You can create your application as described in this topic, in which case the application manifest file is created for you by the tooling, or you can create your application using Apache Ant.

### About this task

OSGi bundles are packaged as Java archive (.jar) files. A single OSGi application is packaged in an enterprise bundle archive (.eba) file, just as an enterprise application is packaged in an enterprise archive (.ear) file. In this example application, the bundles are packaged directly in the .eba file. However the .eba file does not have to contain the bundles; they can be pulled in at run time. For an OSGi application deployed to WebSphere Application Server, a bundle can be located in the .eba file, or in the WebSphere Application Server internal bundle repository, or in an external bundle repository. Every .eba file contains an application manifest (APPLICATION.MF) file, which contains the metadata that defines the application. It lists the bundles that the application uses, and says where each bundle is located.

IBM Rational Application Developer Version 8 provides graphical support for creating and packaging bundles. The sample procedure below uses this tool. You can also use other tools, and the steps are adaptable to other tools.

This sample procedure creates a simple hello-world OSGi application called `com.ibm.ws.eba.helloWorld`, in which the two bundles `com.ibm.ws.eba.helloWorldService` and `com.ibm.ws.eba.helloWorldClient` are packaged together in an .eba file.

When you deploy and start this application, it prints the greeting message “OSGi Service: Hello World!” to the system output log.

## Procedure

1. Create an OSGi application project.
   a. Click **File** > **New** > **Project**. The Select a wizard panel is displayed.
   b. Click **OSGi** > **OSGi Application Project**, then click **Next**. The OSGi Application Project panel is displayed.
   c. Configure the project.
      - For **Project name**, enter `com.ibm.ws.eba.helloWorld`.
      - Ensure that **Use default location** is selected.
      - Ensure that **Add project to working sets** is cleared.
   d. Click **Next**.
   e. In the Contained Bundles list, select `com.ibm.ws.eba.helloWorldService 1.0.0` and `com.ibm.ws.eba.helloWorldClient 1.0.0`

      For more information about these bundles, see “Creating a service bundle” on page 956 and “Creating a client bundle” on page 958.
   f. Click **Finish**.
2. Optional: Deploy and test the OSGi application project on a server running inside IBM Rational Application Developer.

   If you are using IBM Rational Application Developer Version 8, you can deploy to a local machine without first exporting the OSGi application as an EBA file. This is typically how you would test your application. If you are using another tool, omit this step.
   a. Right-click the project name then select **Run As** > **Run on Server**. The Run On Server panel is displayed.
   b. Configure the Run On Server panel:
      1) For server type, select **IBM** > **WebSphere Application Server v8.0**.
      2) For server host name, enter a valid TCP/IP host name. For example, enter the TCP/IP hostname for your computer or enter `localhost`.
      3) For server name, enter the name by which you want to refer to the server within IBM Rational Application Developer.
      4) For server runtime environment, select **WebSphere Application Server v8.0**. If this option is not available in the list, complete the following steps:
         a) Click **Add**.
         b) Navigate to *app_server_root* for the installation of WebSphere Application Server.
         c) Click **Finish**.
      5) Click **Next**.

      The WebSphere Application Server Settings panel is displayed.
   c. Configure the WebSphere Application Server Settings panel:
      1) For profile name, select the profile that you use with OSGi Applications.
      2) For application server name, verify that the application server name for your profile is displayed. By default, the first application server for a profile is called `server1`.
      3) Click **Next**.

      The list of configured OSGi application projects is displayed.
   d. Check that your OSGi application project is in the list of configured projects.
   e. Click **Finish**.
   f. Start the OSGi application:

1) Click the **Servers** tab. If the tab is not already visible, open it by selecting **Window** > **Show View** > **Servers**.
2) On the **Servers** tab, right-click your application server then select **Start**.

The server starts, your application is published and started, and the following output is displayed on the **Console** tab:

```
[4/15/10 14:07:33:295 GMT] 00000023 SystemOut O Client: Start...
[4/15/10 14:07:33:581 GMT] 00000023 SystemOut O OSGi Service: Hello World!
[4/15/10 14:07:33:581 GMT] 00000023 SystemOut O Client: End...
```

3. Export the project as an EBA file.
   a. Right-click the project name, then select **Export** > **OSGi** > **OSGi Application EBA**.
   b. Enter a location for the exported file, then name the file `com.ibm.ws.eba.helloWorld.eba`.
   c. Click **Finish**.

## Results

You have completed the detailed instructions for developing a simple OSGi application. This application consists of two bundles: one bundle defines a hello service, and the other is a client bundle that uses this service to produce the message “OSGi Service: Hello World!”. Your application uses the OSGi service registry to share the hello service between the defining bundle and the client bundle. All interactions with the service registry are handled through Blueprint.

## What to do next

You are now ready to deploy and start your OSGi application outside of IBM Rational Application Developer, by completing the following steps:

1. Deploy your OSGi application as a business-level application.
2. Start your business-level application.
3. Check the system output log for the greeting message “OSGi Service: Hello World!”.

You can use the administrative console or wsadmin commands to deploy and start an OSGi application in WebSphere Application Server. For information about how to do this for any OSGi application, see “Deploying an OSGi application as a business-level application” on page 964 and Starting your business-level application. When you check the system output log, you should see the following message:

```
[4/15/10 14:07:33:295 GMT] 00000023 SystemOut O Client: Start...
[4/15/10 14:07:33:581 GMT] 00000023 SystemOut O OSGi Service: Hello World!
[4/15/10 14:07:33:581 GMT] 00000023 SystemOut O Client: End...
```

## Creating an OSGi application using Apache Ant

You can use the Apache Ant (Ant) command-line tool to package bundles together into an OSGi application.

### Before you begin

This topic assumes that you understand how to use the Ant build tooling, and that you have already created the bundles and the application manifest file that you want to package together as an OSGi application.

For a detailed overview of creating an OSGi application, and instructions on how to do this using IBM Rational Application Developer Version 8 or similar tooling, see “Creating an OSGi application” on page 961.

### About this task

The code example in this topic shows the syntax for using the Ant zip task to package a set of bundles and an application manifest (APPLICATION.MF) file into an enterprise bundle archive (.eba) file.

### Example

```
<zip destfile="${output.dir}/myExample.eba" basedir="${basedir}">
    <filename name="META-INF/APPLICATION.MF"/>
    <fileset dir="${basedir}">
        <include name="*.jar"/>
    </fileset>
</zip>
```

This example packages the META-INF/APPLICATION.MFfile into the EBA file, and also includes all files ending in ".jar" (that is, the bundles).

${output.dir} and ${basedir} refer to the following Ant properties:

- **output.dir** is user-defined, and specifies the output directory for your build.
- **basedir** is predefined, and specifies the directory that contains the Ant build.xml file.

### What to do next

You can use the administrative console or wsadmin commands to deploy and start an OSGi application in WebSphere Application Server. See "Deploying an OSGi application as a business-level application" and Starting your business-level application.

## Deploying an OSGi application as a business-level application

Import an OSGi application as an enterprise bundle archive (EBA) asset, then add the asset to a business-level application by creating a composition unit. Optionally, add a composite bundle extension to the composition unit.

### Before you begin

This topic assumes that you have already created an enterprise OSGi application packaged as an EBA file, for example as described in "Creating an OSGi application" on page 961. You might also have developed a composite bundle extension, as described in Extending a deployed OSGi application.

As well as specifying the configuration information for the EBA asset through the following procedure, you can also change it later as described in Modifying the configuration of an OSGi composition unit. For example, if you update a bundle in an EBA asset, or replace a composite bundle extension, you might introduce a resource that needs additional configuration, such as a new or changed Blueprint resource reference, or security role mapping.

### About this task

To deploy an OSGi application in WebSphere Application Server, you import your OSGi application (EBA file) as an asset and create an empty business-level application. You then add a composition unit to the business-level application. This composition unit consists of the new EBA asset plus configuration information for the context roots, virtual hosts, security role mappings, and web application or Blueprint resource bindings for your OSGi application. The composition unit can also include composite bundle extensions.

**Note:**

- An EBA file can be imported into only one asset.
- An EBA asset can be added to only one business-level application.

- One or more composite bundle extensions can be added to a composition unit.

A business-level application is scoped to cell scope, therefore only one instance of a given OSGi application can be deployed in a cell.

This topic describes the specific task of deploying an OSGi application and any composite bundle extensions as a business-level application. The more generalized task of creating any business-level application is described in Creating business-level applications.

Each step can be completed using either the administrative console or wsadmin commands. You can also create an empty business-level application or add a composition unit using programming.

## Procedure

1. Import the EBA file as an asset.

   **Note:** You can import the asset before or after you create the empty business-level application. An EBA file can be imported into only one asset.

   To import the EBA file using the administrative console, navigate to **Applications** > **New Application** > **New Asset**. For more information, see Importing assets.

   To import the EBA file using the importAsset command, enter (for example) the following command:

   ```
   AdminTask.importAsset(["-storageType", "FULL",
                          "-source", com.ibm.ws.eba.helloWorldService.eba])
   ```

   For more information, see the step “Import assets to your configuration” in topic Setting up business-level applications using wsadmin scripting.

   **Notes:**

   - When you import the EBA file as an asset, it is checked for any bundle dependencies. If the OSGi application has dependencies on bundles that are not included in the EBA file, the dependencies are resolved against any configured bundle repositories. Asset registration cannot complete unless all missing dependencies are available from configured bundle repositories.
   - When asset registration completes, if the asset requires bundles to be downloaded from bundle repositories, a warning message is displayed telling you to save your changes to the master configuration after completing the asset import. When you save changes, the missing dependencies are downloaded from the configured bundle repositories.
   - If the asset uses Java 2 security, the security permissions are displayed. This information comes from the `META-INF/permissions.perm` file for your application. For more information, see Java 2 security and OSGi Applications.
   - Do not add the asset to a business-level application until the bundle download has completed. You can view the download status of the bundles from the administrative console, or by calling the areAllDownloadsComplete () method of the BundleCacheManager MBean. See Interacting with the OSGi bundle cache.

2. Create an empty business-level application.

   To create an empty business-level application using the administrative console, navigate to **Applications** > **New Application** > **New Business Level Application**. For more information, see the step “Create an empty business-level application” in topic Creating business-level applications with the console.

   To create an empty business-level application using the createEmptyBLA command, enter (for example) the following command:

   ```
   AdminTask.createEmptyBLA('[-name "helloWorld"
                              -description "helloWorld OSGi sample"]')
   ```

For more information, see the step “Create an empty business-level application” in topic Setting up business-level applications using wsadmin scripting.

To create an empty business-level application using programming, see Creating an empty business-level application using programming.

3. Add the EBA asset to the business-level application as a composition unit.

   An EBA asset can be added to only one business-level application. An OSGi composition unit consists of an EBA asset, (optionally) one or more composite bundle extensions, and some or all of the following configuration information:

   - Mappings from the composition unit to a target application server, web server or cluster.
   - Configuration of the application's session manager, context roots or virtual hosts.
   - Bindings to any associated web applications or blueprint resource references.
   - Mappings from security roles to particular users or groups.

   To add the asset to the business-level application as a composition unit, use one of the following methods:

   - “Adding an EBA asset to a composition unit using the administrative console.”
   - “Adding an EBA asset to a composition unit using wsadmin commands” on page 969.
   - Adding a composition unit using programming.

4. Optional: Add a composite bundle as an extension to the composition unit.

   After you import the enterprise bundle archive (EBA) file for your OSGi application as an asset, you can update versions of existing bundles but you cannot add extra bundles to the asset. However, after you have added the asset as a composition unit to a business-level application, you can extend the business-level application by adding one or more composite bundles to the composition unit.

5. Save your changes to the master configuration.

   If you are using wsadmin commands, enter the following command:

   ```
   AdminConfig.save()
   ```

## What to do next

You are now ready to start your business-level application.

## Adding an EBA asset to a composition unit using the administrative console

Use the administrative console to add a composition unit that consists of a previously-imported EBA asset plus configuration information. The configuration information can include HTTP session management, context roots, virtual hosts, security roles, run-as roles, and web application or Blueprint resource reference bindings for your OSGi application.

### Before you begin

You can add an EBA asset to a business-level application by using the administrative console as described in this topic, or by using the addCompUnit command as described in “Adding an EBA asset to a composition unit using wsadmin commands” on page 969.

An EBA asset can be added to only one business-level application. A business-level application is scoped to cell scope, therefore only one instance of a given OSGi application can be deployed in a cell.

This task makes the following assumptions:

- You have already imported the EBA file as an asset (as described in “Deploying an OSGi application as a business-level application” on page 964), then saved your changes to the master configuration (which causes any bundle dependencies to be downloaded from configured bundle repositories).
- You have already defined the target virtual hosts. To check existing virtual hosts by using the administrative console, click **Environment** > **Virtual hosts**.

- You have already created the JCA authentication alias that you want to associate with each Blueprint resource reference. To check existing JCA authentication aliases using the administrative console, click **Security** > **Global security** > **[Authentication] Java Authentication and Authorization Service** > **J2C authentication data**.

## About this task

An OSGi composition unit consists of an EBA asset, (optionally) one or more composite bundle extensions, and some or all of the following configuration information:

- Mappings from the composition unit to a target application server, web server or cluster.
- Configuration of the application's session manager, context roots or virtual hosts.
- Bindings to any associated web applications or blueprint resource references.
- Mappings from security roles to particular users or groups.

You use the Set options settings wizard to add a new composition unit to a business-level application. The contents of the asset determine the specific steps in the wizard. This topic describes the main elements that you configure when adding an EBA asset. For a general description of all the elements that the wizard might prompt you to configure, see Creating business-level applications with the console.

As well as specifying the configuration information for the EBA asset through the following procedure, you can also change it later as described in Modifying the configuration of an OSGi composition unit. For example, if you update a bundle in an EBA asset, or replace a composite bundle extension, you might introduce a resource that needs additional configuration, such as a new or changed Blueprint resource reference, or security role mapping.

## Procedure

1. Start the administrative console.
2. Add the previously-imported asset (the `.eba` file) as a deployed asset.
   a. If you have just created a new business-level application, the general properties for the business-level application are already displayed, including the option **[Deployed assets] Add** > **Add Asset**. Otherwise, navigate to **Applications** > **Application Types** > **Business-level applications** > ***application_name*** > **[Deployed assets] Add** > **Add Asset**. A list of available assets is displayed.
   b. Select the asset to add, then click **Continue**. The Set options settings wizard is displayed.
3. Wizard step: Set options.

   Change the composition unit settings as needed, then click **Next**. For more information, see Set options settings.
4. Wizard step: Map composition unit to a target.

   Select the deployment target application server or web server. For more information, see Map target settings.
5. Wizard step: Map context roots.

   Select a web application bundle (WAB) from the list, then enter the context root for the WAB. For example, `/sample`. For more information, see Context root for web application bundles [Settings].
6. Wizard step: Map modules to virtual hosts.

   The list of available WABs in this asset is displayed. For each WAB, you can change the associated virtual host by selecting a different one from the list. If you specify an existing virtual host in the `ibm-web-bnd.xml` or `.xmi` file for a given WAB, the specified virtual host is set by default. Otherwise, the default virtual host setting is `default_host`. For more information, see Virtual hosts for web application bundles [Settings].
7. Wizard step: Security role to user/group mapping.

Change the security mapping as needed. For more information, see Security role to user or group mapping [Settings].

8. Wizard step: Map RunAs roles to users

   You can map a specified user identity and password to a RunAs role. This enables you to specify application-specific privileges for individual users, so that they can run specific tasks using another user identity. For more information, see Map RunAs roles to users [Collection].

9. Wizard step: Bind Blueprint resource references.

   The list of available Blueprint resource references in this asset is displayed. For each reference, you can optionally select an authentication alias from the list. Default authentication aliases (from `ibm-eba-bnd.xml` files) are offered only if they exist on every target server or cluster. For more information, see Blueprint resource reference bindings [Settings].

10. Wizard step: Web module message destination and resource environment reference bindings.

    The list of available web application message destination and resource environment references in this asset is displayed. That is, resources of type message-destination-ref (message destination reference) or resource-env-ref (resource environment reference), as defined in the Java specification JSR-250: Common Annotations for the Java Platform. For each reference, specify the JNDI name under which the resource is known in the runtime environment. For more information, see Web module message destination and resource environment reference bindings [Settings].

11. Wizard step: Web module resource reference bindings.

    The list of available web application resource references in this asset is displayed. That is, resources of type resource-ref (resource reference), as defined in the Java specification JSR-250: Common Annotations for the Java Platform. For each reference, specify the JNDI name under which the resource is known in the runtime environment. Optionally, set authentication properties and extended data source custom properties, which affect how the resource is accessed at run time. To specify the JNDI name mapping, either type the JNDI name into the box, or click **Browse...** then select the resource reference from the list of available resources. To modify the authentication method or set extended data source custom properties, select a single reference then click **Modify Resource Authentication Method...** or **Extended Properties...**. For more information, see Web module resource reference bindings [Settings].

12. Wizard step: Summary

    A summary of your selections is displayed. To complete the creation of the composition unit, click **Finish**. If there are settings that you want to change, click **Previous** to review the settings.

13. Save your changes to the master configuration.

## Results

The product creates composition units for the application, module, or shared library relationships. The unit names are shown in lists of deployed assets on the settings page of your business-level application. To view the settings page, click **Applications** > **Application Types** > **Business-level applications** > ***application_name***.

## What to do next

**Note:** After you import the enterprise bundle archive (EBA) file for your OSGi application as an asset, you can update versions of existing bundles but you cannot add extra bundles to the asset. However, after you have added the asset as a composition unit to a business-level application, you can extend the business-level application by adding one or more composite bundles to the composition unit. See Adding or removing extensions for an OSGi composition unit.

You are now ready to start your business-level application

## Adding an EBA asset to a composition unit using wsadmin commands

You can use the addCompUnit command and the AdminConfig commands to add a composition unit that consists of a previously-imported enterprise bundle archive (EBA) asset plus configuration information. The configuration information can include HTTP session management, context roots, virtual hosts, security roles, run-as roles, and web application or Blueprint resource reference bindings for your OSGi application.

### Before you begin

You can add an EBA asset to a business-level application by using wsadmin commands as described in this topic, or by using the administrative console as described in “Adding an EBA asset to a composition unit using the administrative console” on page 966.

An EBA asset can be added to only one business-level application. A business-level application is scoped to cell scope, therefore only one instance of a given OSGi application can be deployed in a cell.

This task makes the following assumptions:

- You have already imported the EBA file as an asset (for example by using the importAsset command as described in step 2 of Setting up business-level applications using wsadmin scripting), then saved your changes to the master configuration (which causes any bundle dependencies to be downloaded from configured bundle repositories).
- You have already defined the target virtual hosts. To check existing virtual hosts using the wsadmin tool, issue the following jython command:

  ```
  print AdminConfig.list('VirtualHost')
  ```
- You have already created the JCA authentication alias that you want to associate with each Blueprint resource reference.

### About this task

An OSGi composition unit consists of an EBA asset, (optionally) one or more composite bundle extensions, and some or all of the following configuration information:

- Mappings from the composition unit to a target application server, web server or cluster.
- Configuration of the application's session manager, context roots or virtual hosts.
- Bindings to any associated web applications or blueprint resource references.
- Mappings from security roles to particular users or groups.

To create and configure all elements of the composition unit except the HTTP session manager, you use the addCompUnit command. To configure the HTTP session manager, you use the AdminConfig commands to configure the deployed object represented by the *appDeploy* variable. The composition unit must be created before the session management options can be applied to it, so you must run the addCompUnit command before you configure the HTTP session manager.

As well as specifying the configuration information for the EBA asset through the following procedure, you can also change it later as described in Modifying the configuration of an OSGi composition unit using wsadmin commands. For example, if you update a bundle in an EBA asset, or replace a composite bundle extension, you might introduce a resource that needs additional configuration, such as a new or changed Blueprint resource reference, or security role mapping.

### Procedure

1. Create and configure all elements of the composition unit except the HTTP session manager.

   Each of the following substeps describes the syntax for adding a single element to the composition unit. However, to create the composition unit you run the addCompUnit command only once. Therefore, when you run the command, you must combine these elements together. An example of the combined syntax is given after the separate substeps.

For several of the elements, the values you specify include bundle identifiers. If your EBA asset includes or references composite bundles, the command syntax is slightly different. For clarity, the differences for composite bundles are described, step by step, in a linked topic.

a. Add the previously-imported asset (the `.eba` file) as a deployed asset.

The parameters for this aspect of the command are as follows:

**-blaID**
Specifies the configuration ID of the business-level application.

**-cuSourceID**
Specifies the ID of the EBA asset that is being added to the business-level application.

**-CUOptions**
Specifies the following additional properties for the composition unit.

- parentBLA
- backingID
- name
- description
- startingWeight
- startedOnDistributed
- restartBehaviorOnUpdate

**-MapTargets**
Specifies additional properties for the composition unit target mapping. That is, it specifies the deployable unit URI (which, for an EBA asset, is `ebaDeploymentUnit`) and the target node and server, or the target cluster. To add an additional target, you use the plus sign character ( + ) as a prefix.

**-ActivationPlanOptions**
Specifies additional properties for the composition unit activation plan. That is, it specifies the deployable unit URI and a list of runtime components. For an EBA asset, use default values as shown in the example below.

If the target is one cluster, the jython syntax for this aspect of the command is as follows:

```
AdminTask.addCompUnit('[
  -blaID WebSphere:blaname=bla_name
  -cuSourceID WebSphere:assetname=asset_name.eba
  -CUOptions [
    [WebSphere:blaname=bla_name.eba
    WebSphere:assetname=asset_name.eba
    cu_name "optional_cu_description" 1 false DEFAULT]]
  -MapTargets [[ebaDeploymentUnit WebSphere:cluster=cluster_name]]
  -ActivationPlanOptions [[default ""]]
  ...
]')
```

For example:

```
AdminTask.addCompUnit('[
  -blaID WebSphere:blaname=helloWorldService
  -cuSourceID WebSphere:assetname=com.ibm.ws.eba.helloWorldService.eba
  -CUOptions [
    [WebSphere:blaname=helloWorldService.eba
    WebSphere:assetname=com.ibm.ws.eba.helloWorldService.eba
    com.ibm.ws.eba.helloWorldService_0001.eba "" 1 false DEFAULT]]
  -MapTargets [[ebaDeploymentUnit WebSphere:cluster=cluster1]]
  -ActivationPlanOptions [[default ""]]
  ...
]')
```

If the target is two servers, the jython syntax for this aspect of the command is as follows::

```
AdminTask.addCompUnit('[
  -blaID WebSphere:blaname=bla_name
  -cuSourceID WebSphere:assetname=asset_name.eba
  -CUOptions [
    [WebSphere:blaname=bla_name.eba
    WebSphere:assetname=asset_name.eba
    cu_name "optional_cu_description" 1 false DEFAULT]]
  -MapTargets [
    [ebaDeploymentUnit WebSphere:node=node_name,server=server_name+
                       WebSphere:node=node2_name,server=server2_name]]
  -ActivationPlanOptions [[default ""]]
  ...
]')
```

For example:

```
AdminTask.addCompUnit('[
  -blaID WebSphere:blaname=helloWorldService
  -cuSourceID WebSphere:assetname=com.ibm.ws.eba.helloWorldService.eba
  -CUOptions [
    [WebSphere:blaname=helloWorldService.eba
    WebSphere:assetname=com.ibm.ws.eba.helloWorldService.eba
    com.ibm.ws.eba.helloWorldService_0001.eba "" 1 false DEFAULT]]
  -MapTargets [[ebaDeploymentUnit WebSphere:node=node01,server=server1+
                                  WebSphere:node=node01,server=web1]]
  -ActivationPlanOptions [[default ""]]
  ...
]')
```

b. Define WAB context roots.

Context roots determine where the web pages of a particular web application bundle (WAB) are found at run time. The context root that you specify here is combined with the defined server mapping to compose the full URL that you enter to access the pages of the WAB. For example, if the application server default host is www.example.com:8080 and the context root of the WAB is /sample, the web pages are available at www.example.com:8080/sample.

The jython syntax for this aspect of the command is as follows.

**Note:** For composite bundles, the syntax is slightly different. See Step: Define context roots for web application bundles (WABs) in composite bundles.

The bundles listed under the **ContextRootStep** need to be all the WABs contained in the OSGi application.

```
AdminTask.addCompUnit('[
  ...
  -ContextRootStep [
    [bundle_symbolic_name_1 bundle_version_1 context_root_1]
    [bundle_symbolic_name_2 bundle_version_2 context_root_2]]
  ...
]')
```

For example, for an EBA file that contains two WABs (`com.ibm.ws.eba.helloWorldService.web` at version 1.0.0, which is to be mapped to `/hello/web`, and `com.ibm.ws.eba.helloWorldService.withContextRoot` at version 0.9.0, which is to be mapped to `/hello/service`), this aspect of the command is as follows:

```
AdminTask.addCompUnit('[
  ...
  -ContextRootStep [
    [com.ibm.ws.eba.helloWorldService.web 1.0.0 "/hello/web"]
    [com.ibm.ws.eba.helloWorldService.withContextRoot 0.9.0 "/hello/service"]]
  ...
]')
```

c. Map WABs to virtual hosts.

You use a virtual host to associate a unique port with a web application. The aliases of a virtual host identify the port numbers defined for that virtual host. A port number specified in a virtual host alias is used in the URL that is used to access artifacts such as servlets and JavaServer Page (JSP) files in a web application. For example, the alias `myhost:8080` is the *host_name:port_number* portion of the URL `http://myhost:8080/sample`.

Each WAB that is contained in a deployed asset must be mapped to a virtual host. WABs can be installed on the same virtual host, or dispersed among several virtual hosts.

If you specify an existing virtual host in the `ibm-web-bnd.xml` or `.xmi` file for a given WAB, the specified virtual host is set by default. Otherwise, the default virtual host setting is `default_host`, which provides several port numbers through its aliases:

**80** An internal, insecure port used when no port number is specified
**9080** An internal port
**9443** An external, secure port

Unless you want to isolate your WAB from other WABs or resources on the same node, `default_host` is a suitable virtual host. In addition to `default_host`, WebSphere Application Server provides `admin_host`, which is the virtual host for the administrative console system application. `admin_host` is on port 9060. Its secure port is 9043. Do not select `admin_host` unless the WAB relates to system administration.

The jython syntax for this aspect of the command is as follows.

**Note:** For composite bundles, the syntax is slightly different. See Step: Map WABs in composite bundles to virtual hosts.

```
AdminTask.addCompUnit('[
  ...
  -VirtualHostMappingStep [
    [bundle_symbolic_name_1 bundle_version_1
    web_module_name_1 virtual_host_1]
    [bundle_symbolic_name_2 bundle_version_2
     web_module_name_2 virtual_host_2]]
  ...
]')
```

For example, for an EBA file containing two WABs (`com.ibm.ws.eba.helloWorldService.web` at version 1.0.0, which is to be mapped to `default_host`, and `com.ibm.ws.eba.helloWorldService.withContextRoot` at version 0.9.0, which is to be mapped to `test_host`), this aspect of the command is as follows:

```
AdminTask.addCompUnit('[
  ...
  -VirtualHostMappingStep [
    [com.ibm.ws.eba.helloWorldService.web 1.0.0
    "HelloWorld service" default_host]
    [com.ibm.ws.eba.helloWorldService.withContextRoot 0.9.0
    "HelloWorld second service" test_host]]
  ...
]')
```

d. Map security roles to users or groups.

The jython syntax for this aspect of the command is as follows:

```
AdminTask.addCompUnit('[
  ...
  -MapRolesToUsersStep [
    [role_name everyone?
    all_authenticated_in_realm?
    usernames groups]]
  ...
]')
```

**Key:**

- *role_name* is a role name defined in the application.

- *everyone?* is set to Yes or No, to specify whether or not everyone is in the role.
- *all_authenticated_in_realm?* is set to Yes or No, to specify whether or not all authenticated users can access the application realm.
- *usernames* is a list of WebSphere Application Server user names, separated by the "|" character.
- *groups* is a list of WebSphere Application Server groups, separated by the "|" character.

**Note:** For *usernames*, and *groups*, the empty string "" means "use the default or existing value". The default value is usually that no users or groups are bound to the role. However, when an application contains an `ibm-application-bnd.xmi` file, the default value for *usernames* is obtained from this file. If you are deploying an application that contains an `ibm-application-bnd.xmi` file, and you want to remove the bound users, specify just the "|" character (which is the separator for multiple user names). This explicitly specifies "no users", and therefore guarantees that no users are bound to the role.

For example:

```
AdminTask.addCompUnit('[
  ...
  -MapRolesToUsersStep [
    [ROLE1 No Yes "" ""]
    [ROLE2 No No WABTestUser1 ""]
    [ROLE3 No No "" WABTestGroup1]
    [ROLE4 Yes No "" ""]]
  ...
]')
```

For more information about the -MapRolesToUsersStep option, see the information for the $AdminApp install command “MapRolesToUsers” option. This is the equivalent option for Java EE applications. For more general information, see Security role to user or group mapping.

e. Map RunAs roles to users

You can map a specified user identity and password to a RunAs role. This enables you to specify application-specific privileges for individual users, so that they can run specific tasks using another user identity. The jython syntax for this aspect of the command is as follows:

```
AdminTask.addCompUnit('[
  ...
  -MapRunAsRolesToUsersStep [
    [role_name user_name password]]
]')
```

For example:

```
AdminTask.addCompUnit('[
  ...
  -MapRunAsRolesToUsersStep [
    [Role1 User1 password1]
    [AdminRole User3 password3]]
]')
```

For more information about the -MapRunAsRolesToUsers option, see the information for the $AdminApp install command “MapRunAsRolesToUsers” option. This is the equivalent option for Java EE applications. For more general information, see Map RunAs roles to users.

f. Add authentication aliases to Blueprint resource references.

Blueprint components can access WebSphere Application Server resource references. Each reference is declared in a Blueprint XML file, and can be secured using a Java Platform, Enterprise Edition (Java EE) Connector Architecture (JCA) authentication alias. Each bundle in an OSGi application can contain any number of resource reference declarations in its various Blueprint XML files.

When you secure resource references, those resource references can be bound only to JCA authentication aliases that exist on every server or cluster on which the application is deployed. An OSGi application can be deployed to multiple servers and clusters that are in the same security domain. Therefore, each JCA authentication alias must exist in either the security domain of the target servers and clusters, or the global security domain.

You must declare the resource references in the Blueprint XML file. For example:

```
<blueprint xmlns="http://www.osgi.org/xmlns/blueprint/v1.0.0"
  xmlns:rr="http://www.ibm.com/appserver/schemas/8.0/blueprint/resourcereference">
  <!-- Other Blueprint declarations ... -->

  <rr:resource-reference id="resourceRef"
          interface="javax.sql.DataSource"
          filter="(osgi.jndi.service.name=jdbc/Account)">
    <rr:res-auth>Container</rr:res-auth>
    <rr:res-sharing-scope>Shareable</rr:res-sharing-scope>
  </rr:resource-reference>
</blueprint>
```

This declaration includes the resource reference ID (for example `resourceRef`), the service filter (for example `jdbc/Account`), the authentication type (for example `Container`), and the sharing setting (for example `Shareable`).

The Blueprint resource references to authentication alias bindings for each bundle are stored in a file `ibm-eba-bnd.xml` in the `META-INF` directory of that bundle. If an OSGi application contains any of these files when it is deployed as an asset, these files provide the default authentication alias values that are used when binding the resource references. For example:

```
<eba-bnd xmlns="http://www.ibm.com/blueprintbinding.xsd">
  <resource-ref>
    <jndi-name>jdbc/Acount</jndi-name>
    <authentication-alias>Alias1</authentication-alias>
    <interface>javax.sql.DataSource</interface>
    <authentication>Container</authentication>
    <sharing-scope>Shareable</sharing-scope>
    <id>resourceRef</id>
  </resource-ref>
</eba-bnd>
```

The jython syntax for this aspect of the command is as follows.

**Note:** For composite bundles, the syntax is slightly different. See Step: Add authentication aliases to Blueprint resource references in composite bundles.

```
AdminTask.addCompUnit('[
  ...
  -BlueprintResourceRefBindingStep [
    [
    bundle_symbolic_name
    bundle_version
    blueprint_resource_reference_id
    interface_name
    jndi_name
    authentication_type
    sharing_setting
    authentication_alias_name
    ]]
  ...
]')
```

**Note:** The value for *jndi_name* must match the jndi name that you declare in the **filter** attribute of the resource reference element in the Blueprint XML file.

For example, for an EBA file that contains a bundle `com.ibm.ws.eba.helloWorldService.properties.bundle.jar` at Version 1.0.0, which is to be bound to authentication alias `alias1`, the command is as follows:

```
AdminTask.addCompUnit('[
  ...
  -BlueprintResourceRefBindingStep[
    [com.ibm.ws.eba.helloWorldService.properties.bundle 1.0.0 resourceRef
    javax.sql.DataSource jdbc/Account Container Shareable alias1]]
  ...
]')
```

g. Bind web module message destination and resource environment references.

Binding a resource reference maps a resource dependency of the web application to an actual resource available in the server runtime environment. At a minimum, this can be achieved by using a mapping that specifies the JNDI name under which the resource is known in the runtime environment. By default, the JNDI name is the resource ID that you specified in the `web.xml` file during development of the web application bundle (WAB). Use this option to bind resources of type message-destination-ref (message destination reference) or resource-env-ref (resource environment reference), as defined in the Java specification JSR-250: Common Annotations for the Java Platform.

The jython syntax for this aspect of the command is as follows.

**Note:** For composite bundles, the syntax is slightly different. See Step: Bind web module message destination and resource environment references in composite bundles.

```
AdminTask.addCompUnit('[
  ...
  -WebModuleMsgDestRefs [
    [
    bundle_symbolic_name
    bundle_version
    resource_reference_id
    resource_type
    target_jndi_name
    ]]
  ...
]')
```

For example:

```
AdminTask.addCompUnit('[
  ...
  -WebModuleMsgDestRefs [
    [com.ibm.ws.eba.helloWorldService.web 1.0.0
    jms/myQ javax.jms.Queue
    jms/workQ]
    [com.ibm.ws.eba.helloWorldService.web 1.0.0
    jms/myT javax.jms.Topic
    jms/notificationTopic]]
  ...
]')
```

h. Bind web module resource references.

Binding a resource reference maps a resource dependency of the web application to an actual resource available in the server runtime environment. At a minimum, this can be achieved by using a mapping that specifies the JNDI name under which the resource is known in the runtime environment. By default, the JNDI name is the resource ID that you specified in the `web.xml` file during development of the web application bundle (WAB). Use this option to bind resources of type resource-ref (resource reference), as defined in the Java specification JSR-250: Common Annotations for the Java Platform.

The jython syntax for this aspect of the command is as follows.

**Note:** For composite bundles, the syntax is slightly different. See Step: Bind web module resource references in composite bundles.

```
AdminTask.addCompUnit('[
  ...
  -WebModuleResourceRefs [
    [
    bundle_symbolic_name
    bundle_version
    resource_reference_id
    resource_type
    target_jndi_name
    login_configuration
    login_properties
    extended_properties
    ]]
  ...
]')
```

For example:

```
AdminTask.addCompUnit('[
  ...
  -WebModuleResourceRefs [
    [com.ibm.ws.eba.helloWorldService.web 1.0.0
    jdbc/jtaDs javax.sql.DataSource
    jdbc/helloDs "" "" ""]
    [com.ibm.ws.eba.helloWorldService.web 1.0.0
    jdbc/nonJtaDs javax.sql.DataSource
    jdbc/helloDsNonJta "" "" "extprop1=extval1"]]
  ...
]')
```

**Note:** If you use multiple extended properties, the jython syntax is `"extprop1=extval1,extprop2=extval2"`.

In the following example, the jython syntax from the previous individual substeps is combined so that, by running the addCompUnit command once only, a composition unit is created and added to a business-level application.

**Note:** If your EBA asset includes or references composite bundles, the command syntax is slightly different. For an equivalent example, see Example: Using the addCompUnit command to add an EBA asset that includes composite bundles.

```
AdminTask.addCompUnit('[
  -blaID WebSphere:blaname=helloWorldService
  -cuSourceID WebSphere:assetname=com.ibm.ws.eba.helloWorldService.eba
  -CUOptions [
    [WebSphere:blaname=helloWorldService.eba
    WebSphere:assetname=com.ibm.ws.eba.helloWorldService.eba
    com.ibm.ws.eba.helloWorldService_0001.eba "" 1 false DEFAULT]]
  -MapTargets [[ebaDeploymentUnit WebSphere:cluster=cluster1]]
  -ActivationPlanOptions [[default ""]]
  -ContextRootStep [
    [com.ibm.ws.eba.helloWorldService.web 1.0.0 "/hello/web"]
    [com.ibm.ws.eba.helloWorldService.withContextRoot 0.9.0 "/hello/service"]]
  -VirtualHostMappingStep [
    [com.ibm.ws.eba.helloWorldService.web 1.0.0
    "HelloWorld service" default_host]
    [com.ibm.ws.eba.helloWorldService.withContextRoot 0.9.0
    "HelloWorld second service" test_host]]
  -MapRolesToUsersStep [
    [ROLE1 No Yes "" ""]
    [ROLE2 No No WABTestUser1 ""]
    [ROLE3 No No "" WABTestGroup1]
    [ROLE4 Yes No "" ""]]
  -MapRunAsRolesToUsersStep [
    [Role1 User1 password1]
    [AdminRole User3 password3]]
```

```
  -BlueprintResourceRefBindingStep[
    [com.ibm.ws.eba.helloWorldService.properties.bundle 1.0.0 resourceRef
    javax.sql.DataSource jdbc/Account
    Container Shareable alias1]]
  -WebModuleMsgDestRefs [
    [com.ibm.ws.eba.helloWorldService.web 1.0.0
    jms/myQ javax.jms.Queue
    jms/workQ]
    [com.ibm.ws.eba.helloWorldService.web 1.0.0
    jms/myT javax.jms.Topic
    jms/notificationTopic]]
  -WebModuleResourceRefs [
    [com.ibm.ws.eba.helloWorldService.web 1.0.0 jdbc/jtaDs javax.sql.DataSource
    jdbc/helloDs "" "" ""]
    [com.ibm.ws.eba.helloWorldService.web 1.0.0 jdbc/nonJtaDs javax.sql.DataSource
    jdbc/helloDsNonJta "" "" "extprop1=extval1"]]
]')
```

2. Configure the HTTP session manager.

   To configure the HTTP session manager, you use the AdminConfig commands to configure the deployed object represented by the *appDeploy* variable. Session management for OSGi applications is configured in the same way as for enterprise applications, except for a minor difference in syntax when getting the deployed object.

   a. Get the deployed object.

      Use the instructions given in Configuring applications for session management using scripting. Note that, for enterprise applications, you use the following two line script:

      ```
      deployments = AdminConfig.getid('/Deployment:myApp/')
      appDeploy = AdminConfig.showAttribute(deployments, 'deployedObject')
      ```

      For OSGi applications, the equivalent script is the following single line:

      ```
      appDeploy = AdminTask.getOSGiApplicationDeployedObject('-cuName cu_name')
      ```

      where *cu_name* is the name of the composition unit. For example:

      ```
      appDeploy = AdminTask.getOSGiApplicationDeployedObject('
        -cuName com.ibm.ws.eba.helloWorldService_0001.eba')
      ```

   b. Create the session management options.

      Use the instructions given in Configuring applications for session management using scripting. The command usage for creating the session management options is exactly the same for enterprise applications and OSGi applications.

### What to do next

After using these commands, save your changes to the master configuration by using the following command:

```
AdminConfig.save()
```

**Note:** After you import the enterprise bundle archive (EBA) file for your OSGi application as an asset, you can update versions of existing bundles but you cannot add extra bundles to the asset. However, after you have added the asset as a composition unit to a business-level application, you can extend the business-level application by adding one or more composite bundles to the composition unit. See Adding or removing extensions for an OSGi composition unit using wsadmin commands.

You are now ready to start your business-level application.

***Adding an EBA asset that includes composite bundles using the addCompUnit command:***

You can use the addCompUnit command to add a composition unit that contains a previously-imported enterprise bundle archive (EBA) asset plus configuration information. If the EBA asset includes composite bundles, the command syntax is slightly different.

**Before you begin**

For a full description of how you specify this configuration information, see “Adding an EBA asset to a composition unit using wsadmin commands” on page 969. When you work through that task, each step where the syntax is different for composite bundles is linked to an equivalent step in this task.

**About this task**

An OSGi composition unit includes an EBA asset and some or all of the following configuration information:

- Mappings from the composition unit to a target application server, web server or cluster.
- Configuration of the application's session manager, context roots or virtual hosts.
- Bindings to any associated web applications or blueprint resource references.
- Mappings from security roles to particular users or groups.

For several of the elements, the values you specify include bundle identifiers. If your EBA asset includes or references composite bundles, the command syntax is slightly different. The differences for composite bundles are described in the following steps.

**Procedure**

- Define context roots for web application bundles (WABs) in composite bundles.

  The jython syntax for this aspect of the command is as follows:

  ```
  AdminTask.addCompUnit('[
    ...
    -ContextRootStep [
      [bundle_symbolic_name_1 bundle_version_1 context_root_1]
      [bundle_symbolic_name_2 bundle_version_2 context_root_2]]
    ...
  ]')
  ```

  For composite bundles, the bundle symbolic name has the following syntax:

  ```
  CBA.symbolic.Name_CBA.bundle.version/WAB.symbolic.name
  ```

  For example, for a composite bundle `com.ibm.ws.eba.helloWorldCBA` at version 1.0.0 that contains two WABs (`com.ibm.ws.eba.helloWorldService.web` at version 1.0.0, which is to be mapped to `/hello/web`, and `com.ibm.ws.eba.helloWorldService.withContextRoot` at version 0.9.0, which is to be mapped to `/hello/service`), this aspect of the command is as follows:

  ```
  AdminTask.addCompUnit('[
    ...
    -ContextRootStep [
      [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web 1.0.0
      "/hello/web"]
      [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.withContextRoot 0.9.0
      "/hello/service"]]
    ...
  ]')
  ```

  **Note:** For bundles other than composite bundles, the syntax is slightly different. See Step: Define WAB context roots.

- Map WABs in composite bundles to virtual hosts.

  The jython syntax for this aspect of the command is as follows:

```
AdminTask.addCompUnit('[
  ...
  -VirtualHostMappingStep [
    [bundle_symbolic_name_1 bundle_version_1
    web_module_name_1 virtual_host_1]
    [bundle_symbolic_name_2 bundle_version_2
     web_module_name_2 virtual_host_2]]
  ...
]')
```

For composite bundles, the bundle symbolic name has the following syntax:

```
CBA.symbolic.Name_CBA.bundle.version/WAB.symbolic.name
```

For example, for a composite bundle `com.ibm.ws.eba.helloWorldCBA` at version 1.0.0 that contains two WABs (`com.ibm.ws.eba.helloWorldService.web` at version 1.0.0, which is to be mapped to `default_host`, and `com.ibm.ws.eba.helloWorldService.withContextRoot` at version 0.9.0, which is to be mapped to `test_host`), this aspect of the command is as follows:

```
AdminTask.addCompUnit('[
  ...
  -VirtualHostMappingStep [
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web
    1.0.0 "HelloWorld service" default_host]
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.withContextRoot
    0.9.0 "HelloWorld second service" test_host]]
  ...
]')
```

**Note:** For bundles other than composite bundles, the syntax is slightly different. See Step: Map WABs to virtual hosts.

- Add authentication aliases to Blueprint resource references in composite bundles.

  The jython syntax for this aspect of the command is as follows.

```
AdminTask.addCompUnit('[
  ...
  -BlueprintResourceRefBindingStep [
    [
    bundle_symbolic_name
    bundle_version
    blueprint_resource_reference_id
    interface_name
    jndi_name
    authentication_type
    sharing_setting
    authentication_alias_name
    ]]
  ...
]')
```

**Notes:**

  – For composite bundles, the bundle symbolic name has the following syntax:

    ```
    CBA.symbolic.Name_CBA.bundle.version/embedded_bundle.symbolic.name
    ```

  – The value for *jndi_name* must match the jndi name that you declare in the **filter** attribute of the resource reference element in the Blueprint XML file.

For example, for a composite bundle `com.ibm.ws.eba.helloWorldCBA` at version 1.0.0 that contains a bundle `com.ibm.ws.eba.helloWorldService.properties.bundle.jar` at Version 1.0.0, which is to be bound to authentication alias `alias1`, the command is as follows:

```
AdminTask.addCompUnit('[
  ...
  -BlueprintResourceRefBindingStep[
```

```
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.properties.bundle
    1.0.0 resourceRef javax.sql.DataSource jdbc/Account Container Shareable alias1]]
  ...
]')
```

**Note:** For bundles other than composite bundles, the syntax is slightly different. See Step: Add authentication aliases to Blueprint resource references.

- Bind web module message destination and resource environment references in composite bundles.

  The jython syntax for this aspect of the command is as follows

```
AdminTask.addCompUnit('[
  ...
  -WebModuleMsgDestRefs [
    [
    bundle_symbolic_name
    bundle_version
    resource_reference_id
    resource_type
    target_jndi_name
    ]]
  ...
]')
```

  For composite bundles, the bundle symbolic name has the following syntax:

```
CBA.symbolic.Name_CBA.bundle.version/WAB.symbolic.name
```

  For example:

```
AdminTask.addCompUnit('[
  ...
  -WebModuleMsgDestRefs [
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web
    1.0.0
    jms/myQ javax.jms.Queue
    jms/workQ]
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web
    1.0.0
    jms/myT javax.jms.Topic
    jms/notificationTopic]]
  ...
]')
```

  **Note:** For bundles other than composite bundles, the syntax is slightly different. See Step: Bind web module message destination and resource environment references.

- Bind web module resource references in composite bundles.

  The jython syntax for this aspect of the command is as follows.

```
AdminTask.addCompUnit('[
  ...
  -WebModuleResourceRefs [
    [
    bundle_symbolic_name
    bundle_version
    resource_reference_id
    resource_type
    target_jndi_name
    login_configuration
    login_properties
    extended_properties
    ]]
  ...
]')
```

  For composite bundles, the bundle symbolic name has the following syntax:

```
CBA.symbolic.Name_CBA.bundle.version/WAB.symbolic.name
```

For example:

```
AdminTask.addCompUnit('[
  ...
  -WebModuleResourceRefs [
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web
    1.0.0
    jdbc/jtaDs javax.sql.DataSource
    jdbc/helloDs "" "" ""]
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web
    1.0.0
    jdbc/nonJtaDs javax.sql.DataSource
    jdbc/helloDsNonJta "" "" "extprop1=extval1"]]
  ...
]')
```

**Notes:**

- If you use multiple extended properties, the jython syntax is `"extprop1=extval1,extprop2=extval2"`.
- For bundles other than composite bundles, the syntax is slightly different. See Step: Bind web module resource references.

### Example

In the following example, the jython syntax from the previous steps is combined with the additional steps described in “Adding an EBA asset to a composition unit using wsadmin commands” on page 969 so that, by running the addCompUnit command once only, a composition unit is created and added to a business-level application. In the example, an EBA file `com.ibm.ws.eba.helloWorldService.eba` contains a composite bundle with symbolic name `com.ibm.ws.eba.helloWorldCBA`, at version `1.0.0`. This composite bundle contains two WABs:

- `com.ibm.ws.eba.helloWorldService.web`, at version 1.0.0
- `com.ibm.ws.eba.helloWorldService.withContextRoot`, at version 0.9.0

The composite bundle also contains a bundle with symbolic name `com.ibm.ws.eba.helloWorldService.properties.bundle`, at version 1.0.0.

```
AdminTask.addCompUnit('[
  -blaID WebSphere:blaname=helloWorldService
  -cuSourceID WebSphere:assetname=com.ibm.ws.eba.helloWorldService.eba
  -CUOptions [
    [WebSphere:blaname=helloWorldService.eba
    WebSphere:assetname=com.ibm.ws.eba.helloWorldService.eba
    com.ibm.ws.eba.helloWorldService_0001.eba "" 1 false DEFAULT]]
  -MapTargets [[ebaDeploymentUnit WebSphere:cluster=cluster1]]
  -ActivationPlanOptions [[default ""]]
  -ContextRootStep [
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web 1.0.0
    "/hello/web"]
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.withContextRoot 0.9.0
    "/hello/service"]]
  -VirtualHostMappingStep [
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web
    1.0.0 "HelloWorld service" default_host]
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.withContextRoot
    0.9.0 "HelloWorld second service" test_host]]
  -MapRolesToUsersStep [
    [ROLE1 No Yes "" ""]
    [ROLE2 No No WABTestUser1 ""]
    [ROLE3 No No "" WABTestGroup1]
    [ROLE4 Yes No "" ""]]
  -MapRunAsRolesToUsersStep [
```

```
    [Role1 User1 password1]
    [AdminRole User3 password3]]
  -BlueprintResourceRefBindingStep[
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.properties.bundle
    1.0.0 resourceRef javax.sql.DataSource jdbc/Account Container Shareable alias1]]
  -WebModuleMsgDestRefs [
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web
    1.0.0
    jms/myQ javax.jms.Queue
    jms/workQ]
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web
    1.0.0
    jms/myT javax.jms.Topic
    jms/notificationTopic]]
  -WebModuleResourceRefs [
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web
    1.0.0
    jdbc/jtaDs javax.sql.DataSource
    jdbc/helloDs "" "" ""]
    [com.ibm.ws.eba.helloWorldCBA_1.0.0/com.ibm.ws.eba.helloWorldService.web
    1.0.0
    jdbc/nonJtaDs javax.sql.DataSource
    jdbc/helloDsNonJta "" "" "extprop1=extval1"]]
]')
```

# Debugging bundles at run time using the command-line console

You can use the wsadmin-based OSGi Applications command-line console to explore or debug the bundles associated with a specific OSGi application or shared bundle framework.

## About this task

The OSGi Applications command-line console is a set of wsadmin commands that you can use to explore or debug a specific set of bundles running on an application server. As an aid to debugging applications in a test environment, the console also includes commands to start and stop bundles.

Every OSGi application that is currently running is viewed by the command-line console as a separate framework. On each application server that is running an OSGi application, there is also one shared bundle framework.

To work with a framework that is currently running, you first connect to the framework.

## Procedure

1. Start the OSGi Applications command-line console.

   At a command prompt, run the `osgiApplicationConsole.bat` command (for Windows systems) or the `osgiApplicationConsole.sh` command (for Linux systems). You can run this command from the *app_server_root*`/bin` directory or from any *profile_root*`/bin` directory. The command takes the following optional parameters:

   **-h** The host name of the target machine. For example, `machine1.hursley.ibm.com`.

   **-o** The port number of the SOAP port of the target server. For example, `8880`.

   **-u** The user ID, if the wsadmin connection is secured.

   **-p** The password, if the wsadmin connection is secured.

   For example:

   *app_server_root*`/bin/osgiApplicationConsole -h machine1.hursley.ibm.com -o 8880`

The wsadmin command prompt is displayed. This instance of wsadmin recognizes OSGi Applications console commands.

2. Connect to an available framework.

   You use the connect command to connect to a specific framework.

   If you know the framework name and version number, and the node and server on which the framework is running, you can use this information to connect. For example:

   ```
   wsadmin>connect("com.ibm.ws.eba.helloWorldService.eba", "1.0.0", "wasNode1", "server1")
   ```

   Alternatively, use the list command to list all available frameworks and to provide a unique ID for each framework, then use this ID to connect. For example:

   a. List all available frameworks:

      ```
      wsadmin>list()
      ```

      If you are connecting to an individual application server, this command might generate the following system response:

      ```
      ID   Bundle                                Version  Node      Server
      0    SharedBundles                         7.0.0    wasNode1  server1
      1    com.ibm.ws.eba.helloWorldService.eba  1.0.0    wasNode1  server1
      2    com.ibm.ws.eba.obr.fep.eba5.eba       1.0.0    wasNode1  server1
      3    com.ibm.ws.eba.wab.componenttest      1.0.0    wasNode1  server1
      ```

   b. Connect to the `com.ibm.ws.eba.helloWorldService.eba` framework:

      ```
      wsadmin>connect(1)
      ```

      If the command completes successfully it generates the following system responses:

      ```
      CWSAJ0035I: Connecting to framework com.ibm.ws.eba.helloWorldService.eba_1.0.0
      on node wasNode1 and server server1.
      CWSAJ0036I: Successfully connected to framework com.ibm.ws.eba.helloWorldService.eba_1.0.0.
      ```

   To connect to a different framework, run the connect command again. You do not need to disconnect from one framework before connecting to another framework.

3. Work with the connected framework.

   Use one or more of the following commands to work with the framework to which you are connected:

   - List all available frameworks, and indicate the currently connected framework.

     Use the list command:

     ```
     wsadmin>list()
     ```

     This command might generate the following system response:

     ```
     ID   Bundle                                Version  Node      Server
     0    SharedBundles                         7.0.0    wasNode1  server1
     1    com.ibm.ws.eba.helloWorldService.eba  1.0.0    wasNode1  server1  <== Connected
     2    com.ibm.ws.eba.obr.fep.eba5.eba       1.0.0    wasNode1  server1
     3    com.ibm.ws.eba.wab.componenttest      1.0.0    wasNode1  server1
     ```

   - Display summary information about each of the bundles in the framework.

     Use the ss command:

     ```
     wsadmin>ss()
     ```

     **Note:** “ss” stands for “short status”.
     This command might generate the following system response:

     ```
     ID      State       Bundle
     0       ACTIVE      org.eclipse.osgi_3.6.1.R36x_v20100806
     1       ACTIVE      com.ibm.samples.websphere.osgi.blog.app_1.0.0
     2       ACTIVE      com.ibm.samples.websphere.osgi.blog_1.0.0
     3       ACTIVE      com.ibm.samples.websphere.osgi.blog.persistence_1.0.0
     4       ACTIVE      com.ibm.samples.websphere.osgi.blog.web_1.0.0
     5       ACTIVE      com.ibm.samples.websphere.osgi.blog.api_1.0.0
     ```

- Display comprehensive information about all of the bundles in the framework, and the services that they register or consume.

  Use the bundles command:

  ```
  wsadmin>bundles()
  ```

  This command might generate the following system response.

  **Note:** Information about the bundles that you included in your application is listed as bundle 2 and subsequent bundles. Bundles 0 and 1 are system artefacts; do not modify or rely on these bundles. Although the detail for bundle 0 is not shown in the following example, this bundle typically generates much more information than the other bundles.

```

```

- Display comprehensive information about a given bundle in the framework.

  Use the bundle command. Specify the ID of the bundle that you want to examine. The bundle ID values are one of the outputs of the ss command.

  This command lists the information associated with the specified bundle. For example the bundle symbolic name, the bundle version, the services that the bundle registers, the services that are consumed by the bundle, and whether the bundle is a fragment or a host bundle.

  For example:

  ```
  wsadmin>bundle(3)
  ```

  This command might generate the following system response:

  ```
  com.ibm.samples.websphere.osgi.blog.persistence_1.0.0 [3]
    Id=3, Status=ACTIVE
  Location=reference:file:/C:/IBM/WebSphere/AppServer/profiles/profile01/

      org.eclipse.osgi_3.6.1.R36x_v20100806 [0]
      com.ibm.samples.websphere.osgi.blog.api_1.0.0 [5]
  ```

- Display header information about a given bundle.

  Use the headers command. Specify the ID of the bundle that you want to examine. The bundle ID values are one of the outputs of the ss command.

For example:

```
wsadmin>headers(2)
```

This command might generate the following system response:

```
Ant-Version = Apache Ant 1.7.1
Bundle-ActivationPolicy = lazy
Bundle-ManifestVersion = 2
Bundle-Name = Blog Core Services Bundle
Bundle-SymbolicName = com.ibm.samples.websphere.osgi.blog
Bundle-Vendor = IBM
Bundle-Version = 1.0.0
Created-By = 2.4 (Your Corporation)
Import-Package = com.ibm.samples.websphere.osgi.logging;version="[1.0.0,1.1.0)",
com.ibm.samples.websphere.osgi.blog.api;version="[1.0.0,1.1.0)",
com.ibm.samples.websphere.osgi.blog.comment.persistence.api;version="[1.0.0,1.1.0)",
com.ibm.samples.websphere.osgi.blog.persistence.api;version="[1.0.0,1.1.0)"
Manifest-Version = 1.0
```

- Display information about the packages that are imported or exported by the framework.

  Use the packages command. Optionally, specify either or both of the following parameters to select a particular package or subset of packages:

  **bundle ID**
  Display information about the exported packages for this bundle.

  The bundle ID values are one of the outputs of the ss command.

  **package name**
  Display information about the specified package.

  Command syntax:

  ```
  wsadmin>packages()
  wsadmin>packages(bundle_id)
  wsadmin>packages(package_name)
  ```

  Example using a bundle ID:

  ```
  wsadmin>packages(5)
  ```

  This command might generate the following system response:

  ```
  com.ibm.samples.websphere.osgi.blog.persistence.api; version="1.0.0"
  <com.ibm.samples.websphere.osgi.blog.api_1.0.0 [5]>
    com.ibm.samples.websphere.osgi.blog_1.0.0 [2] imports
    com.ibm.samples.websphere.osgi.blog.persistence_1.0.0 [3] imports
  com.ibm.samples.websphere.osgi.blog.comment.persistence.api; version="1.0.0"
  <com.ibm.samples.websphere.osgi.blog.api_1.0.0 [5]>
    com.ibm.samples.websphere.osgi.blog_1.0.0 [2] imports
  com.ibm.samples.websphere.osgi.blog.api; version="1.0.0"
  <com.ibm.samples.websphere.osgi.blog.api_1.0.0 [5]>
    com.ibm.samples.websphere.osgi.blog_1.0.0 [2] imports
    com.ibm.samples.websphere.osgi.blog.web_1.0.0 [4] imports
  ```

  Example using a package name:

  ```
  wsadmin>packages("com.ibm.samples.websphere.osgi.blog.comment.persistence.api")
  ```

  This command might generate the following system response:

  ```
  com.ibm.samples.websphere.osgi.blog.comment.persistence.api; version="1.0.0"
  <com.ibm.samples.websphere.osgi.blog.api_1.0.0 [5]>
    com.ibm.samples.websphere.osgi.blog_1.0.0 [2] imports
  ```

- Display information about the services that are currently registered by the framework. For each service this information includes the service interfaces, the bundle that registered the service, and any bundles that consume the service.

  Use the services command. Optionally, specify either or both of the following parameters to select a particular service or subset of services:

**service ID**
Display information about a specified service.

**filter**
Display information about all services that match the filter.

The filter must comply with the OSGi filter format as defined in section 3.2.7 of the OSGi Service Platform Release 4 Version 4.2 Core Specification.

Command syntax:

```
wsadmin>services()
wsadmin>services(service_id)
wsadmin>services("(&(prop1=value_1)(prop2=value_2))")
```

Example using a service ID:

```
wsadmin>services(2)
```

This command might generate the following system response:

```
{org.osgi.service.packageadmin.PackageAdmin}={service.id=2,
service.ranking=2147483647,service.vendor=Eclipse.org - Equinox,
service.pid=0.org.eclipse.osgi.framework.internal.core.PackageAdminImpl}
  Registered by bundle: org.eclipse.osgi_3.6.1.R36x_v20100806 [0]
  Bundles using service:
    org.eclipse.osgi_3.6.1.R36x_v20100806 [0]
```

Example using a single property filter:

```
wsadmin>services("(objectClass=org.osgi.service.packageadmin.PackageAdmin)")
```

This command might generate the following system response:

```
{org.osgi.service.packageadmin.PackageAdmin}={service.id=2,
service.ranking=2147483647,service.vendor=Eclipse.org - Equinox,
service.pid=0.org.eclipse.osgi.framework.internal.core.PackageAdminImpl}
  Registered by bundle: org.eclipse.osgi_3.6.1.R36x_v20100806 [0]
  Bundles using service:
    org.eclipse.osgi_3.6.1.R36x_v20100806 [0]
```

Example using a multiple property filter:

```
wsadmin>services("(&(objectClass=javax.resource.Referenceable)(ibm.private.jndi.object=true))")
```

This command might generate the following system response:

```
{java.lang.reflect.InvocationHandler,com.ibm.websphere.rsadapter.WSDataSource,java.sql.Wrapper,
javax.sql.CommonDataSource,javax.resource.Referenceable,javax.sql.DataSource}={service.id=35,
osgi.jndi.service.name=jdbc/pgc,ibm.private.jndi.object=true}
  Registered by bundle: org.eclipse.osgi_3.6.1.R36x_v20100806 [0]
  No bundles using service.

```

- Update the cached runtime information about the framework.

  It can take some time for the system to gather the runtime information about the framework and the bundles running within it. Therefore, when you run the `osgiApplicationConsole` command, the command-line console caches the runtime information. If you make changes to the currently

selected framework, for example by updating or adding bundles, these changes are not reflected in the output of the command-line console commands until you run the refresh command.

**Note:** You can also update this runtime information by restarting the OSGi Applications command-line console. However, you then have to reconnect to the framework. It is quicker to use the refresh command.

Command syntax:

```
wsadmin>refresh()
```

- Stop a bundle.

  Use the stop command to stop the bundle specified by a given bundle ID. The bundle ID values are one of the outputs of the ss command.

  **Note:**

  – The OSGi Applications command line console is intended primarily as a method of debugging applications. In a production environment, you would normally use the administrative console or equivalent administrative commands to start and stop applications.

  – Do not use the stop command on any bundles under the shared bundle framework, on system bundles, or on the bundles that represent system artefacts (bundle ID 0 and 1), because this can cause serious errors.

  For example:

  ```
  wsadmin>stop(5)
  ```

  This command might generate the following system response:

  ```
  CWSAJ0042I: Stopping Bundle com.ibm.samples.websphere.osgi.blog.api_1.0.0.
  CWSAJ0034I: Bundle com.ibm.samples.websphere.osgi.blog.api stopped successfully.
  ```

- Start a bundle.

  Use the start command to start the bundle specified by a given bundle ID. The bundle ID values are one of the outputs of the ss command.

  **Note:**

  – The OSGi Applications command line console is intended primarily as a method of debugging applications. In a production environment, you would normally use the administrative console or equivalent administrative commands to start and stop applications.

  – Do not use the start command on any bundles under the shared bundle framework, on system bundles, or on bundles that represent applications (bundle ID 0 and 1), because this can cause serious errors.

  For example:

  ```
  wsadmin>start(5)
  ```

  This command might generate the following system response:

  ```
  CWSAJ0040I: Starting Bundle com.ibm.samples.websphere.osgi.blog.api_1.0.0.
  CWSAJ0032I: Bundle com.ibm.samples.websphere.osgi.blog.api started successfully.
  ```

- Display help information about the console commands.

  Use the help command to display a summary of the runtime commands and their uses.

  Command syntax:

  ```
  wsadmin>help()
  ```

  This command generates the following system response:

```
CWSAJ0025I:      OSGi application console

Display commands: These commands work only if connected to a framework

ss()                - This command gives the summary information about the installed bundles.
bundles()           - This command gives comprehensive information about the installed bundles.
packages()          - This command gives information about the imported/exported packages.
services()          - This command gives information about the registered Services.

bundle(<bundleID>)  - This command gives information about the specified bundle
headers(<bundleID>) - This command gives information about the headers associated with the
                      specified bundle
packages(<bundle ID>) - This command gives information about the exported packages for this bundle.
packages(<package Name>) - This command gives information about the specified package.
services(<service ID>) - This command gives information about the specified service.
services(<OSGI Filter>) - This command gives information about the services matching the filter.

refresh() - This command refreshes the internal OSGi application console cache with the latest
            information about the state of the framework.

Framework commands:

list() - This command lists the available frameworks that you can connect to.
connect(<Framework id>) - This command connects to the specified framework.
connect(<Bundle Name>, <Bundle Version>, <Node Name>, <Server Name>)
                 - This command connects to the specified framework.

Controlling Bundles:

start(<bundleID>) - This command starts the requested bundle.
stop(<bundleID>   - This command stops the requested bundle.
```

# Developing a composite bundle

A composite bundle groups shared bundles together into aggregates. It provides one or more packages at specific versions to an OSGi application. You can also extend a deployed application by adding one or more composite bundles to the composition unit for the application. You can use OSGi application tooling to develop a composite bundle.

## About this task

When you want to ensure consistent behavior from a set of shared bundles in an OSGi application, you use a composite bundle to provide that set of bundles to the application. If a required package or service is available at the same version from both a bundle and a composite bundle, the provisioning process selects the package or service from the composite bundle.

When you want to extend a deployed business-level application that contains an OSGi application, and you don't want to stop the application or modify the underlying EBA asset, you add one or more composite bundles to the composition unit.

A composite bundle is packaged as a composite bundle archive (CBA) file. This is a compressed archive file with a `.cba` file extension. If the composite bundle is part of an enterprise OSGi application, the CBA file can be directly contained within the enterprise bundle archive (EBA) file for the application, or pulled in by reference from the internal bundle repository or from an external repository that can process composite bundles. A composite bundle can directly contain bundles in its CBA file. It can also include by reference bundles that are hosted alongside the CBA file within the same EBA file, or bundles that are installed in the same bundle repository.

A composite bundle is described in a composite bundle manifest file, `META-INF/COMPOSITEBUNDLE.MF`. This manifest file lists the OSGi bundles that are directly contained in the composite bundle, and the reference bundles that are hosted alongside the composite bundle in the same EBA file, or in the same bundle repository.

If you want to use your composite bundle to extend a deployed application, you must install the CBA file in the internal bundle repository or in an external repository that can process composite bundles. If you install a composite bundle in a bundle repository, and the composite bundle includes bundles by reference, you must ensure that the referenced bundles are also available in the same repository. If you use the internal bundle repository, and the composite bundle directly contains bundles, the contained bundles are not listed separately and are only available as part of the composite bundle. For more information, see Composite bundles.

IBM Rational Application Developer Version 8 provides graphical support for creating and packaging composite bundles. You can also use other tools.

### Procedure

1. Develop the bundles.

   See “Creating a service bundle” on page 956 and “Creating a client bundle” on page 958. You might also want to explore the sample OSGi applications.
2. Create the composite bundle manifest.

   Most OSGi application tooling, including IBM Rational Application Developer Version 8, helps you create the composite bundle manifest. See also Example: OSGi composite bundle manifest file.
3. Package the directly-contained bundles and the composite bundle manifest as a compressed file with a `.cba` file extension.

   **Note:** The file extension must be `.cba`, but the composite bundle name need not include “cba”.
4. Check that all referenced bundles are available in the EBA file (if the composite bundle is part of an enterprise OSGi application), or in a bundle repository that can process composite bundles (such as the internal bundle repository).

   See Administering bundles in the internal bundle repository or Administering bundles in the internal bundle repository using wsadmin commands.
5. Add the CBA file to the EBA file or to the bundle repository.

### What to do next

- If you have configured an enterprise OSGi application to use your composite bundle, you can now import the application as an asset. See “Deploying an OSGi application as a business-level application” on page 964.
- If you want to use your composite bundle to extend a composition unit, see Adding or removing extensions for an OSGi composition unit.

## Converting existing applications to OSGi applications

You can convert an enterprise application or a Spring application to an OSGi application.

### Procedure

- Convert an enterprise application to an OSGi application.
- Convert a Spring application to an OSGi application.

## Converting an enterprise application to an OSGi application

You can automatically convert an enterprise archive (EAR) file that contains web application archive (WAR) files to an enterprise bundle archive (EBA) file.

### Before you begin

Ensure that the enterprise application is suitable for conversion to an OSGi application. Check whether any manual conversion steps are required first. See Conversion of an enterprise application to an OSGi application.

### About this task

You can automatically convert a web application to an OSGi application, that is, you can convert an EAR file that contains only WAR files. For other enterprise applications, you might require manual migration steps before you use the following procedure.

### Procedure

1. Rename the EAR file (`.ear`) to an EBA file (`.eba`).
2. In WebSphere Application Server, import the EBA file as an asset.
3. Optional: Modify any converted Java 2 security settings.

   When you convert an application from Java EE to OSGi, any existing `was.policy` file is converted into a `permissions.perm` file to be used with the OSGi permissions framework, and all permissions are promoted to the application level. If you need finer granularity, you can modify the file after conversion. For more information, see Java 2 security and OSGi Applications.

### Results

The WAR files are automatically converted to web application bundles (WABs). Any Java 2 security `was.policy` file is converted into a `permissions.perm` file. Any Utility JAR or EJB JAR files are not converted and the EJB function is not directly accessible in the EJB container.

## Converting a Spring application to an OSGi application

To convert an application that is created using the Spring Framework to an OSGi application and move from the Spring Framework to standards-based technologies, you must modify the application manually. If a Spring application contains only web application archive (WAR) files, you can convert it automatically to run in OSGi Applications, but it still uses the Spring Framework.

### About this task

In a Spring application, the Spring Framework manages features such as transactions, persistence, and dependency injection, and handles the communication between the servlets in the web container and the classes that handle the business logic of the application.

After you convert the application to an OSGi application that uses OSGi Applications support, the Blueprint Container manages the transactions, persistence and dependency injection.

If the application is an enterprise archive (EAR) file that contains only web application archive (WAR) files, you can convert it automatically. You might convert a Spring application in this way if a WAR file uses other library JAR files that must remain unchanged for the application to work. See “Converting an enterprise application to an OSGi application” on page 990.

Otherwise, you need to identify the Spring components and replace them with the equivalent code to make them plain old Java objects (POJOs), then modify the relevant XML files so that the Blueprint container manages those objects.

To convert a Spring application, you change it as follows:

- Create a well-defined interface to delegate to. The interface represents the classes that handle the business logic of the application.

- Create a service for each class, so that the servlet in the web container can use them.
- Change code that is specific to the Spring Framework in the classes to use the equivalent in Java EE, for example Java EE persistence classes.
- Create a handler servlet and interface to replace those from the Spring Framework.
- Modify XML and manifest files to use syntax that is correct for the Blueprint Container.

At the end of each step, the application is still usable, so you can decide whether to make all, or just some, of these changes.

The following procedure describes these steps in more detail.

## Procedure

1. Create a well defined interface to delegate to, for example to replace a dispatcher servlet in the Spring application. The following example replaces the Spring HttpRequestHandler interface in an example application with the MyApplicationHandler interface.
   a. Create an interface to replace the Spring HttpRequestHandler interface.

```
package com.ibm.ws.eba.example.springconversion;

import javax.servlet.http.HttpServletRequest;
import javax.servlet.http.HttpServletResponse;

interface MyApplicationHandler {

 void setMyApplicationHandle(MyApplicationUserInterface b);

 void handleRequest(HttpServletRequest request, HttpServletResponse response)
throws Exception;

}
```

   b. In each class that imports and implements the Spring HttpRequestHandler interface, implement the new interface. For example, change the following code:

```
implements HttpRequestHandler
```

      to :

```
implements MyApplicationHandler
```

   c. If the method creates an exception that is not in a base Java package, for example a ServletException exception, you can change it to use more general exception handling and avoid additional OSGi package imports. For example, change the following code:

```
handleRequest(HttpServletRequest request, HttpServletResponse response)
throws ServletException, IOException
```

      to:

```
handleRequest(HttpServletRequest request, HttpServletResponse response)
throws Exception
```

   To replace the Spring interface with this new interface, you must also replace the servlet, as described in step 4 on page 994.
2. At this point, you could continue to use the Spring classes and use the Blueprint Container to manage those objects. To do this, change the `blueprint.xml` file, as described in step 7 on page 995.

   The configuration for dependency injection that the Blueprint Container uses is similar to the configuration for the Spring Framework. For example, if the Spring Framework calls the setMyApplicationHandle method to inject the *MyApplicationUserInterface* variable, this injection continues to work in the Blueprint Container, as long as the `blueprint.xml` file is configured correctly.
3. Change the managed bean that handles persistence to use standard Java EE persistence classes. In the following example, the Spring JpaTemplate interface handles persistence. It is equally valid if using JPA directly through an entity manager.

a. Replace the JpaTemplate interface with Java EE persistence classes. For example, remove the following import statement:

```
import org.springframework.orm.jpa.JpaTemplate;
```

Replace it with the following import statements:

```
import javax.persistence.EntityManager;
import javax.persistence.PersistenceContext;
import javax.persistence.Query;
```

b. Use the relevant calls that are available in the API for those interfaces. For example, to replace the JpaTemplate code with EntityManager code, remove the following code:

```
@PersistenceUnit(unitName = "springExample")
  private JpaTemplate jpaTemplate;

  public void setJpaTemplate(JpaTemplate j)
  {
    jpaTemplate = j;
  }
```

Replace it with the following code:

```
@PersistenceContext(unitName = "myApplication")
  private EntityManager em;
  public void setEntityManager(EntityManager e) {
    em = e;
  }
```

c. If a persistence unit is inside a web application, separate the persistence unit from the WAR and create a persistence bundle. The persistence bundle must contain the entity classes and the `persistence.xml` file. The bundle manifest must have a Meta-Persistence header that points to the persistence unit, as shown in the following example:

```
Manifest-Version: 1.0
Bundle-ManifestVersion: 2
Bundle-Name: MyPersistenceBundle
Bundle-SymbolicName: com.ibm.ws.eba.example.persistence
Bundle-Version: 1.0.0
Meta-Persistence: WEB-INF/classes/META-INF/persistence.xml
Import-Package: javax.persistence
```

d. Replace each instance of a call from the bean that handles persistence with an equivalent call that uses the EntityManager interface, the Query interface, or both. For example, in the example Spring application, the following code snippet shows two methods that call the jpaTemplate.find method:

```
@SuppressWarnings("unchecked")
public boolean checkEMailAddressUniqueness(String emailAddress)
{
  boolean result = false;

  List<UserInfo> users = jpaTemplate.find(uniqueEmailAddressQuery, emailAddress);

  if (users.isEmpty()) {
    result = true;
  }

  return result;
}

public boolean checkUsernameUniqueness(String username)
{
  boolean result = false;

  UserInfo user = jpaTemplate.find(UserInfo.class, username);

  if (user == null) {
    result = true;
```

```
  }

  return result;
}
```

The following code snippet shows replacement code:

```
private static final String uniqueEmailAddressQuery = "select u from UserInfo u
where u.emailAddress = ?1";

@SuppressWarnings("unchecked")
public boolean checkEMailAddressUniqueness(String emailAddress)
{
  boolean result = false;

  Query q = em.createQuery(uniqueEmailAddressQuery);
  q.setParameter(1, emailAddress);

  List<UserInfo> users = q.getResultList();

  if (users.isEmpty()) {
    result = true;
  }

return result;
}

public boolean checkUsernameUniqueness(String username)
{
  boolean result = false;

  UserInfo user = em.find(UserInfo.class, username);

  if (user == null) {
    result = true;
  }

    return result;
  }
```

4. Create and register a handler servlet to replace the one from the Spring Framework.
   a. Create a servlet to forward requests to the appropriate handler in the Blueprint Container to process the business logic. This servlet is managed by the web container. The JNDI lookup is constructed as follows:

      `osgi:service/`*`class_name`*`/`*`ldap_filter`*

      The following code snippet creates the MyApplicationHandlerServlet servlet that passes an HTTP request to the MyApplicationHandler class in the Blueprint Container:

```
package com.ibm.ws.eba.example.springconversion;

import javax.naming.InitialContext;
import javax.naming.NamingException;
import javax.servlet.http.HttpServlet;
import javax.servlet.http.HttpServletRequest;
import javax.servlet.http.HttpServletResponse;

public class MyApplicationHandlerServlet extends HttpServlet {

 private static final long serialVersionUID = -3705932907251688199L;

 @Override
 public void service(HttpServletRequest request, HttpServletResponse response)
 {
  // Get servlet name
  String servletName = this.getServletConfig().getServletName();

  // Get business logic class from service registry that is
```

```
 // associated with the servlet

 try {
      InitialContext ic = new InitialContext();
      MyApplicationHandler myApplicationLogicClass = (MyApplicationHandler)
      ic.lookup("osgi:service/com.ibm.ws.eba.example.springconversion.
      MyApplicationHandler/(servlet.name="+servletName+")");
      myApplicationLogicClass.handleRequest(request, response);
  } catch (NamingException e) {
      e.printStackTrace();
  } catch (Exception e) {
          // TODO Auto-generated catch block
          e.printStackTrace();
 }

}

}
```

b. Register the new servlet by changing the servlet classes to define the servlet you just created, rather than the Spring servlet. To do this, modify the `web.xml` file in the `WEB-INF` folder of the WAR file.

   For example, change the following servlet definition in the `web.xml` file:

```
<servlet>
    <servlet-name>RegistrationServlet</servlet-name>
 <servlet-class> org.springframework.web.context.support.HttpRequestHandlerServlet
 </servlet-class>
  </servlet>
```

   to:

```
<servlet>
    <servlet-name>RegistrationServlet</servlet-name>
 <servlet-class>com.ibm.ws.eba.example.springconversion.MyApplicationHandlerServlet
</servlet-class>
  </servlet>
```

c. Delete the following elements from the `web.xml` file:

```
<context-param>
<listener>
```

5. Separate the persistence unit from the EAR file and create a persistence bundle. The persistence bundle must contain the entity classes and the `persistence.xml` file. The bundle manifest must have a Meta-Persistence header that points to the persistence unit, as shown in the following example:

```
Manifest-Version: 1.0
Bundle-ManifestVersion: 2
Bundle-Name: MyPersistenceBundle
Bundle-SymbolicName: com.ibm.ws.eba.example.persistence
Bundle-Version: 1.0.0
Meta-Persistence: WEB-INF/classes/META-INF/persistence.xml
Import-Package: javax.persistence
```

6. If you removed the persistence unit from a WAR file, delete the following element from the `web.xml` file in the `WEB-INF` folder of the WAR file:

```
<persistence-unit-ref>
```

7. Change the XML so that the Blueprint Container manages the objects, rather than the Spring Framework.
   a. Delete the `springapp-service.xml` file in the `WEB-INF` folder of the WAR file.
   b. Create the `OSGI-INF/blueprint/` directory.
   c. Create a file named `blueprint.xml` in the `OSGI-INF/blueprint/` directory. The following code shows an example `blueprint.xml` file:

```
<blueprint xmlns:tx="http://aries.apache.org/xmlns/transactions/v1.0.0"
           xmlns:jpa="http://http://aries.apache.org/xmlns/jpa/v1.0.0">

  <bean id="myApplicationImpl"
    class="com.ibm.ws.eba.example.springconversion.impl.MyApplicationImpl">
    <jpa:context property="entityManager" unitname="myApplication" />
    <tx:transaction method="*" value="Required"/>
  </bean>

  <bean id="RegistrationServlet"
    class="com.ibm.ws.eba.example.springconversion.Registration">
    <tx:transaction method="*" value="Required"/>
    <property name="myApplicationHandle" ref="myApplicationService" />
  </bean>

  <service id="myApplicationService" ref="myApplicationImpl" interface=
     "com.ibm.ws.eba.example.springconversion.MyApplicationUserInterface" />

  <service id="registrationService" ref="RegistrationServlet" interface=
     "com.ibm.ws.eba.example.springconversion.MyApplicationHandler" >
    <service-properties>
      <entry key="servlet.name" value="RegistrationServlet"/>
    </service-properties>
  </service>

</blueprint>
```

8. Update the `persistence.xml` file in the `war/WEB-INF/classes/META-INF/` directory. For example, you can change the JNDI lookups to use a service from a service registry. The following code is an example:

```
<persistence xmlns="http://java.sun.com/xml/ns/persistence"
   xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
   xsi:schemaLocation="http://java.sun.com/xml/ns/persistence
   http://java.sun.com/xml/ns/persistence/persistence_1_0.xsd"
   version="1.0">

   <persistence-unit name="myApplication" transaction-type="JTA">
      <description>Persistence unit for the Spring conversion sample application
      </description>

      <provider>com.ibm.websphere.persistence.PersistenceProviderImpl
      </provider>

      <jta-data-source>osgi:service/javax.sql.DataSource/
        (osgi.jndi.service.name=jdbc/userdb)
      </jta-data-source>
      <non-jta-data-source>osgi:service/javax.sql.DataSource/
        (osgi.jndi.service.name=jdbc/userdbnonjta)
      </non-jta-data-source>
      <class>com.ibm.ws.eba.example.springconversion.Post</class>
      <class>com.ibm.ws.eba.example.springconversion.UserInfo</class>
      <exclude-unlisted-classes/>
   </persistence-unit>
</persistence>
```

9. Create the enterprise bundle archive (EBA) structure for the application.
   a. Create a `META-INF` directory in the root of the project and create an application manifest, `APPLICATION.MF`. The following code shows an example application manifest file:

```
Manifest-Version: 1.0
Application-ManifestVersion: 1.0
Application-Name: MyApplication
Application-SymbolicName: com.ibm.ws.eba.example.springconversion
Application-Version: 1.0
Application-Content: com.ibm.ws.eba.example.springconversion
```

   b. Delete the `context.xml` file from the `war/META-INF/` directory.

c. In the `war/META-INF/` directory, create a bundle manifest file, `MANIFEST.MF`. The following code shows an example bundle manifest file:

```
Manifest-Version: 1.0
Bundle-ManifestVersion: 2
Bundle-Name: MyApplication
Bundle-SymbolicName: com.ibm.ws.eba.example.springconversion
Bundle-Version: 1.0.0
Bundle-Vendor: IBM
Bundle-ClassPath: WEB-INF/classes,
 WEB-INF/lib/aspectjrt.jar,WEB-INF/lib/aspectweaver.jar,
 WEB-INF/lib/commons-collections-3.2.jar,WEB-INF/lib/commons-lang-2.1.jar,
 WEB-INF/lib/JSON4J.jar,WEB-INF/lib/jstl.jar,WEB-INF/lib/jta.jar,
 WEB-INF/lib/openjpa-1.3.0-SNAPSHOT.jar,WEB-INF/lib/persistence.jar,
 WEB-INF/lib/serp-1.13.1.jar,WEB-INF/lib/standard.jar
Web-ContextPath: myApplication
Import-Package: javax.servlet;version="2.5",
 javax.servlet.http;version="2.5",
 javax.servlet.jsp;version="2.1",
 javax.servlet.jsp.tagext;version="2.1",
 org.osgi.framework;version="1.5.0",
 javax.persistence
```

# Sample OSGi applications

OSGi Applications support includes sample applications that demonstrate how to write and package bundles into an enterprise bundle archive (EBA) file.

Two sample OSGi applications are provided: “Blog” and “Blabber”. Both applications demonstrate all of the following OSGi Applications features:

- Using Blueprint management.
- Using bean injection.
- Using services from the OSGi service registry.
- Publishing services to the OSGi service registry.
- Using the Java Persistence API (JPA).

The samples are provided in the `OSGi_blogSample.zip` and `OSGi_blabberSample.zip` compressed archive files, which can be downloaded from the Samples download page. The EBA file for each sample application is in the `installableApps` directory of the sample compressed file, and the source code is provided in other subdirectories of the sample compressed file.

For information about how to install and run each sample application, see the `sample_osgi_blog_readme` and `sample_osgi_blabber_readme` respectively. These files are available in the root directory of the associated sample compressed file. They are also available in the information center as topics “OSGi blog sample application” on page 998 and “OSGi blabber sample application” on page 1003.

## Blog sample application

The blog sample application is a traditional blogging application, used for publishing essay-length articles and allowing readers to comment on them. The application contains the following bundles:

- com.ibm.ws.eba.example.blog.persistence.

  This bundle contains JPA-related code, and the interfaces that enable the main application code to update and query blog entries.
- com.ibm.ws.eba.example.blog_1.0.0.

  This bundle contains the main application logic code and interacts between the web front end and the back end persistence code layer.
- com.ibm.ws.eba.example.blog.web.

This bundle contains the static web content and backing Java code for the web front end of the application.

- com.ibm.ws.eba.example.blog.api.

  This bundle contains the API for the sample.
- com.ibm.ws.eba.example.blog.persistence_1.1.0.

  This bundle contains an optional upgraded persistence bundle that also supplies a comment service.

To run the blog sample application, you can use all the bundles that are listed, or all the bundles except the upgraded persistence bundle (the last in the list).

For more information, see "OSGi blog sample application."

### Blabber sample application

The blabber sample application is a microblogging application, used to enable many different people to share brief comments. The application contains the following bundles:

- com.ibm.ws.eba.example.blabber.persistence.

  This bundle contains code that relates to the Java Persistence API (JPA) layer and the interface for the main application code.
- com.ibm.ws.eba.example.blabber.

  This bundle contains the main application code and the code for the web front end of the application.

For more information, see "OSGi blabber sample application" on page 1003.

## OSGi blog sample application

The blog sample application is a traditional blogging application, used for publishing essay-length articles and allowing readers to comment on them. This sample application shows how to write and package bundles into an enterprise bundle archive (EBA) file. The sample includes example code for Blueprint management, bean injection, using and publishing services from and to the OSGi service registry, and the use of Java persistence.

### Before you begin

The blog sample application consists of five bundles, but can be run with four bundles because the fifth bundle is an upgrade to the persistence bundle.

The sample application requires that the supplied `com.ibm.samples.websphere.osgi.logging.api.jar` and `com.ibm.samples.websphere.osgi.logging.impl.jar` bundles are installed into the internal bundle repository. The following procedure describes how to do this. These two JAR files, and the blog sample EBA file, are provided in the `installableApps` directory of the `OSGi_blogSample.zip` compressed archive file.

### About this task

The bundles are divided into the following functional areas:

- `com.ibm.samples.websphere.osgi.blog.persistence`, which contains code relating to the Java Persistence API (JPA) layer, and also contains interfaces that are used by the main application code to update and query blog entries.
- `com.ibm.samples.websphere.osgi.blog_1.0.0`, which contains the main application logic code, and interacts between the web front end and the back end persistence code layer.
- `com.ibm.samples.websphere.osgi.blog.web`, which contains the static web content and backing Java code for the web front end for the application.

- `com.ibm.samples.websphere.osgi.blog.api`, which contains the API for the whole sample.
- `com.ibm.samples.websphere.osgi.blog.persistence_1.1.0`, which contains an upgraded persistence bundle that also supplies a comment service.

You can use scripts to completely install the sample application, or you can use scripts to complete the initial configuration of the application then use the administrative console to install the application into the application server. You can also use, modify and remove the sample, and upgrade the persistence service that is provided by the sample.

## Procedure

Configure and install the blog sample.
You can either configure and install the sample using scripts (the first optional step below), or you can configure the sample using scripts then install the sample using the administrative console (the second optional step below).
The scripts that you use to do this are provided in the `scripts` directory of the `OSGi_blogSample.zip` compressed archive file. The `createBlogDb.sql` script contains the necessary configuration commands to create the required Derby database and associated tables. The `blogSampleInstall.py` script contains the required jython to create data sources, and to install the blog sample with default configuration. You should fully qualify the path to the script if you do not run it from the directory that contains the script.

**Note:** If you have data sources already defined in your environment, and these data sources have the same name as the data sources that are specified in the `blogSampleInstall.py` script, then the sample might not install and run successfully.

In the following steps you must substitute your own values for the variables *app_server_root*, *profileName*, *serverName*, *nodeName*, *blogSample.eba_Location*, *com.ibm.samples.websphere.osgi.logging.api.jar_Location*, *com.ibm.samples.websphere.osgi.logging.impl.jar_Location*, *uncompressed_sample_directory*, and *path_to_ant*.

- Optional: Configure and install the sample using scripts.
  1. Create and configure the “BLOGDB” Derby database and associated tables by running the following command.

     On UNIX platforms:

     ```
     app_server_root/derby/bin/embedded/ij.sh scripts/createBlogDb.sql
     ```

     On Windows platforms:

     ```
     app_server_root\derby\bin\embedded\ij.bat scripts\createBlogDb.sql
     ```

  2. Create the data sources, create the business-level application and import the .eba file as an asset by running the following command.

     **Note:** The target application server must be running before you use this script.

     On UNIX platforms:

     ```
     app_server_root/profiles/profileName/bin/wsadmin.sh
          -f scripts/blogSampleInstall.py fullInstall serverName nodeName
          blogSample.eba_Location
          com.ibm.samples.websphere.osgi.logging.api.jar_Location
          com.ibm.samples.websphere.osgi.logging.impl.jar_Location
     ```

     On Windows platforms:

     ```
     app_server_root\profiles\profileName\bin\wsadmin.bat
          -f scripts\blogSampleInstall.py fullInstall serverName nodeName
          blogSample.eba_Location
          com.ibm.samples.websphere.osgi.logging.api.jar_Location
          com.ibm.samples.websphere.osgi.logging.impl.jar_Location
     ```

- Optional: Configure the sample using scripts, then install the sample using the administrative console.

1. Create and configure the ""BLOGDB" " Derby database and associated tables by running the following command.

   On UNIX platforms:

   ```
   app_server_root/derby/bin/embedded/ij.sh scripts/createBlogDb.sql
   ```

   On Windows platforms:

   ```
   app_server_root\derby\bin\embedded\ij.bat scripts\createBlogDb.sql
   ```

2. Create the data sources by running the following command.

   On UNIX platforms:

   ```
   app_server_root/profiles/profileName/bin/wsadmin.sh
        -f scripts/blogSampleInstall.py setupOnly serverName nodeName
   ```

   On Windows platforms:

   ```
   app_server_root\profiles\profileName\bin\wsadmin.bat
        -f scripts\blogSampleInstall.py setupOnly serverName nodeName
   ```

3. Use the administrative console to add the `com.ibm.samples.websphere.osgi.logging.api.jar` file to the internal bundle repository.
   a. Navigate to **Environment** > **OSGi bundle repositories** > **Internal bundle repository**
   b. Click **New**.
   c. Select the file system that hosts the `com.ibm.samples.websphere.osgi.logging.api.jar` file, then click **Browse**.
   d. Browse to the *uncompressed_sample_dir*`/installableApps` directory.
   e. Select the `com.ibm.samples.websphere.osgi.logging.api.jar` file, then click **OK**.
   f. Click **OK**.
   g. Click **Save**.
4. Repeat the previous step to add the `com.ibm.samples.websphere.osgi.logging.impl.jar` file to the internal bundle repository.
5. Use the administrative console to import the application (EBA file) as an asset, and to configure the business-level application.
   a. Import the asset.
      1) Navigate to **Applications** > **New application** > **New Asset**.
      2) On the Upload asset panel, browse to the *uncompressed_sample_dir*`/installableApps` directory.
      3) Select the `com.ibm.samples.websphere.osgi.blog.eba` file, then click **Next**.
      4) On the Select options for importing an asset panel, click **Next**.
      5) On the Summary panel, click **Finish**.
      6) Click **Save**.
   b. Create the business-level application and add the asset.
      1) Navigate to **Applications** > **New application** > **New Business Level Application**.
      2) On the New Application panel, enter a name for the business-level application. For example, “blog”.
      3) Click **Apply**.
      4) In the Deployed assets pane, click **Add** > **Add Asset**.
      5) Select the `com.ibm.samples.websphere.osgi.blog.eba` asset, then click **Continue**.
      6) On the Set options panel, click **Next**.
      7) Select a target for the composition unit, then click **Next**.
      8) Modify the context root if required, then click **Next**.
      9) Modify the virtual host if required, then click **Next**.
      10) On the Summary panel, click **Finish**.

11) Click **Save**.

6. Start the application.
   a. Select the newly-created business-level application.
   b. Click **Start**.

Use the blog sample.

- Use your browser to navigate to `http://server:port/context_root/` (by default `http://localhost:9080/blog/`). The View blog screen is displayed.
- Register yourself as an Author. You need to do this before you can create blog entries.
  1. Click **Create Author**.
  2. Fill in the form.
  3. Click **Submit**.
- Create a blog entry.
  1. Navigate back to `http://localhost:9080/blog/` (or click **Blog Home**).
  2. Click **Create New Post**.
  3. Fill in the form. Use the email address that you specified when you created the Author.
  4. Click **Submit**.

  The View blog screen is redisplayed, and should contain your post.

Upgrade the persistence service.

To add the new persistence bundle to the blog application, use the administrative console to add the `com.ibm.samples.websphere.osgi.blog.persistence_1.1.0.jar` file to the internal bundle repository, then modify the asset to expect a new bundle version.

- Navigate to **Environment** > **OSGi bundle repositories** > **Internal bundle repository**.
- Click **New**.
- Browse to the *uncompressed_sample_dir*`/installableApps` directory.
- Select the `com.ibm.samples.websphere.osgi.blog.persistence_1.1.0.jar` file, then click **OK**.
- Save your changes to the master configuration.
- Navigate to **Applications** > **Application types** > **Assets**.
- Click **com.ibm.samples.websphere.osgi.blog.eba** to view the asset information.
- Scroll to the end of the asset information, then click **Update bundle versions in this application**.
- Find the `com.ibm.samples.websphere.osgi.blog.persistence` bundle in the list.
- Click the down arrow beside the text “no preference”. You are offered a choice between version 1.0.0 or 1.1.0 of the persistence bundle.
- Select version 1.1.0, then work through the preview, commit and save screens.
- Navigate to **Applications** > **Application types** > **Business-level applications**.
- Stop then restart the blog sample.

  Select the business-level application representing the blog sample application, then click **Stop**. Wait until the status column shows that the application has stopped, then click **Start**.
- Use your browser to navigate to `http://server:port/context_root/` (by default `http://localhost:9080/blog/`) then refresh the screen. The View blog screen is displayed. There is a new option to add comments to blog posts.

Modify the blog sample

All the source code for this application is provided in sub-directories below the *uncompressed_sample_dir* directory. Each part of the project has its own ant `build.xml` script. To build the whole application into a newly-available EBA file, you use the ant `build.xml` file located in the *uncompressed_sample_dir* directory. WebSphere Application Server ships a version of ant in its `bin` directory called `ws_ant`. To build the

sample, you also need several JAR files on the ant classpath. To simplify matters, you can edit the **was.root** property in the supplied `build.properties` file to point to these JAR files.

- Put the following jar files on the ant classpath:
  - `javax.j2ee.persistence.jar`
  - `javax.j2ee.jsp.jar`
  - `javax.j2ee.servlet.jar`

  These JAR files are available in the `plugins` directory of Websphere Application Server. Edit the **was.root** property in the supplied *uncompressed_sample_dir*`/scripts/build.properties` file, and point it to your *app_server_root* directory. If you have copied the jars to another location, modify the **was.root** property to point to this location.
- Run the following ant command from the *uncompressed_sample_dir* directory:

  *path_to_ant* `-propertyfile scripts/build.properties -buildfile build.xml`

  The newly-built binary (EBA file) is in the *uncompressed_sample_dir*`/output` directory.

  **Note:** This is the only location to which this EBA file is written. The script does not overwrite the original binary located in the *uncompressed_sample_dir*`/installableApps` directory.

Remove the blog sample.

To remove the blog sample, you complete the following 3 steps:

1. Remove the application configuration and the data sources, either by using a script (the first optional step below), or by using the administrative console (the second optional step below).
2. Remove the shared logging bundles from the internal bundle repository.
3. Remove the database.

**Note:** Only remove the bundles if you have no other applications installed that use them. Both the blog and blabber sample applications use the shared logging bundles, so if both applications are installed these bundles should not be removed.

The uninstall script is provided in the `scripts` directory of the `OSGi_blogSample.zip` compressed archive file. The `blogSampleUninstall.py` script contains the required jython to remove data sources and to remove the installation of the blog sample with default configuration. You should fully qualify the path to the script if you do not run it from the directory that contains the script.

In the following steps you must substitute your own values for the variables *app_server_root*, and *profileName*.

- Optional: Remove the application configuration and the data sources by running the following command.

  **Note:** The target application server must be running before you use this script.

  On UNIX platforms:

  ```
  app_server_root/profiles/profileName/bin/wsadmin.sh
           -f scripts/blogSampleUninstall.py
  ```

  On Windows platforms:

  ```
  app_server_root\profiles\profileName\bin\wsadmin.bat
           -f scripts\blogSampleUninstall.py
  ```

- Optional: Remove the application configuration and the data sources by using the administrative console.
  1. Remove the application configuration.
     a. Navigate to **Applications** > **Application types** > **Business-level applications**.
     b. Select the business-level application representing the blog sample application, then click **Stop**.

c. Click the business-level application representing the blog sample application to view the configuration details.
d. Select all the deployed assets, then click **Delete**.
e. Click **OK** to confirm removal.
f. Click **Save**.
g. Select the business-level application representing the blog sample application, then click **Delete**.
h. Navigate to **Applications** > **Application types** > **Assets**.
i. Select the `com.ibm.samples.websphere.osgi.blog.eba` asset, then click **Delete**.
j. Click **OK** to confirm removal.
k. Click **Save**.

2. Remove the data sources.
   a. Navigate to **Resources** > **JDBC** > **Data sources**.
   b. Select the two data sources configured for the blog application.
   c. Click **Delete**.
   d. Click **Save**.

- Remove the shared logging bundles from the internal bundle repository by using the administrative console.
  1. Navigate to **Environment** > **OSGi bundle repositories** > **Internal bundle repository**.
  2. Select the following bundles:
     - `com.ibm.samples.websphere.osgi.logging.api.jar`
     - `com.ibm.samples.websphere.osgi.logging.impl.jar`
     - `com.ibm.samples.websphere.osgi.blog.persistence_1.1.0`
  3. Click **Delete**.
  4. Click **Save**.
- Remove the database.

  On UNIX platforms, open a command prompt, then enter the following command:

  ```
  cd app_server_root/derby
  rm -fr BLOGDB
  ```

  On Windows platforms, delete the *app_server_root*`\derby\BLOGDB` directory.

# OSGi blabber sample application

The blabber sample application is a microblogging application, used to enable many different people to share brief comments. This sample application shows how to write and package bundles into an enterprise bundle archive (EBA) file. The sample includes example code for Blueprint management, bean injection, using and publishing services from and to the OSGi service registry, and the use of Java persistence.

## Before you begin

The sample application requires that the supplied `com.ibm.samples.websphere.osgi.logging.api.jar` and `com.ibm.samples.websphere.osgi.logging.impl.jar` bundles are installed into the internal bundle repository. The following procedure describes how to do this. These two JAR files, and the blabber sample EBA file, are provided in the `installableApps` directory of the `OSGi_blabberSample.zip` compressed archive file.

## About this task

The blabber sample application consists of two bundles, divided into the following functional areas:

- `com.ibm.samples.websphere.osgi.blabber.persistence`, which contains code relating to the Java Persistence API (JPA) layer, and also contains the interface that is used by the main application code.

- `com.ibm.samples.websphere.osgi.blabber`, which contains the main application logic code, and interacts between the web front end and the back end persistence code layer.

You can use scripts to completely install the sample application, or you can use scripts to complete the initial configuration of the application then use the administrative console to install the application into the application server. You can also use, modify and remove the sample.

## Procedure

Configure and install the blabber sample.
You can either configure and install the sample using scripts (the first optional step below), or you can configure the sample using scripts then install the sample using the administrative console (the second optional step below).
The scripts that you use to do this are provided in the `scripts` directory of the `OSGi_blabberSample.zip` compressed archive file. The `createblabberDb.sql` script contains the necessary configuration commands to create the required Derby database and associated tables. The `blabberSampleInstall.py` script contains the required jython to create data sources, and to install the blabber sample with default configuration. You should fully qualify the path to the script if you do not run it from the directory that contains the script.

**Note:** If you have data sources already defined in your environment, and these data sources have the same name as the data sources that are specified in the `blabberSampleInstall.py` script, then the sample might not install and run successfully.
In the following steps you must substitute your own values for the variables *app_server_root*, *profileName*, *serverName*, *nodeName*, *blabberSample.eba_Location*, *com.ibm.samples.websphere.osgi.logging.api.jar_Location*, *com.ibm.samples.websphere.osgi.logging.impl.jar_Location*, *uncompressed_sample_directory*, and *path_to_ant*.

- Optional: Configure and install the sample using scripts.
  1. Create and configure the “BLABBERDB” Derby database and associated tables by running the following command.

     On UNIX platforms:

     ```
     app_server_root/derby/bin/embedded/ij.sh scripts/createBlabberDb.sql
     ```

     On Windows platforms:

     ```
     app_server_root\derby\bin\embedded\ij.bat scripts\createBlabberDb.sql
     ```

  2. Create the data sources, create the business-level application and import the .eba file as an asset by running the following command.

     **Note:** The target application server must be running before you use this script.

     On UNIX platforms:

     ```
     app_server_root/profiles/profileName/bin/wsadmin.sh
          -f scripts/blabberSampleInstall.py fullInstall serverName nodeName
          blabberSample.eba_Location
          com.ibm.samples.websphere.osgi.logging.api.jar_Location
          com.ibm.samples.websphere.osgi.logging.impl.jar_Location
     ```

     On Windows platforms:

     ```
     app_server_root\profiles\profileName\bin\wsadmin.bat
          -f scripts\blabberSampleInstall.py fullInstall serverName nodeName
          blabberSample.eba_Location
          com.ibm.samples.websphere.osgi.logging.api.jar_Location
          com.ibm.samples.websphere.osgi.logging.impl.jar_Location
     ```

- Optional: Configure the sample using scripts, then install the sample using the administrative console.
  1. Create and configure the “"BLABBERDB" ” Derby database and associated tables by running the following command.

On UNIX platforms:

```
app_server_root/derby/bin/embedded/ij.sh scripts/createBlabberDb.sql
```

On Windows platforms:

```
app_server_root\derby\bin\embedded\ij.bat scripts\createBlabberDb.sql
```

2. Create the data sources by running the following command.

   On UNIX platforms:

   ```
   app_server_root/profiles/profileName/bin/wsadmin.sh
        -f scripts/blabberSampleInstall.py setupOnly serverName nodeName
   ```

   On Windows platforms:

   ```
   app_server_root\profiles\profileName\bin\wsadmin.bat
        -f scripts\blabberSampleInstall.py setupOnly serverName nodeName
   ```

3. Use the administrative console to add the `com.ibm.samples.websphere.osgi.logging.api.jar` file to the internal bundle repository.
   a. Navigate to **Environment** > **OSGi bundle repositories** > **Internal bundle repository**
   b. Click **New**.
   c. Select the file system that hosts the `com.ibm.samples.websphere.osgi.logging.api.jar` file, then click **Browse**.
   d. Browse to the *uncompressed_sample_dir*`/installableApps` directory.
   e. Select the `com.ibm.samples.websphere.osgi.logging.api.jar` file, then click **OK**.
   f. Click **OK**.
   g. Click **Save**.
4. Repeat the previous step to add the `com.ibm.samples.websphere.osgi.logging.impl.jar` file to the internal bundle repository.
5. Use the administrative console to import the application (EBA file) as an asset, and to configure the business-level application.
   a. Import the asset.
      1) Navigate to **Applications** > **New application** > **New Asset**.
      2) On the Upload asset panel, browse to the *uncompressed_sample_dir*`/installableApps` directory.
      3) Select the `com.ibm.samples.websphere.osgi.blabber.app.eba` file, then click **Next**.
      4) On the Select options for importing an asset panel, click **Next**.
      5) On the Summary panel, click **Finish**.
      6) Click **Save**.
   b. Create the business-level application and add the asset.
      1) Navigate to **Applications** > **New application** > **New Business Level Application**.
      2) On the New Application panel, enter a name for the business-level application. For example, “blabber”.
      3) Click **Apply**.
      4) In the Deployed assets pane, click **Add** > **Add Asset**.
      5) Select the `com.ibm.samples.websphere.osgi.blabber.app.eba` asset, then click **Continue**.
      6) On the Set options panel, click **Next**.
      7) Select a target for the composition unit, then click **Next**.
      8) Modify the context root if required, then click **Next**.
      9) Modify the virtual host if required, then click **Next**.
      10) On the Summary panel, click **Finish**.
      11) Click **Save**.
6. Start the application.

a. Select the newly-created business-level application.
b. Click **Start**.

Use the blabber sample.

- Use your browser to navigate to `http://server:port/context_root/` (by default `http://localhost:9080/blabber/`). The main blabber screen is displayed.
- Register yourself as a user. You need to do this before you can create blabber entries.
  1. Click **Click here to sign-up!**.
  2. Fill in the form.
  3. Click **Create my account!**.

  The status update home page is displayed.
- Explore the blabber application.

  From the status update home page, you can select any of the following options:
  – Set a status message.
  – Search for and track other users.
  – View your profile.
  – Sign out.

  Within each of the previous options, there is an option to return to the status update home page.

  **Note:**
  – When you enter some status then click **Update**, your status message is displayed on the current page.
  – You can only view or use the tracking option if the application has more than one user.

Modify the blabber sample.

All the source code for this application is provided in sub-directories below the *uncompressed_sample_dir* directory. Each part of the project has its own ant `build.xml` script. To build the whole application into a newly-available EBA file, you use the ant `build.xml` file located in the *uncompressed_sample_dir* directory. WebSphere Application Server ships a version of ant in its `bin` directory called `ws_ant`. To build the sample, you also need several JAR files on the ant classpath. To simplify matters, you can edit the **was.root** property in the supplied `build.properties` file to point to these JAR files.

- Put the following jar files on the ant classpath:
  – `javax.j2ee.persistence.jar`
  – `javax.j2ee.jsp.jar`
  – `javax.j2ee.servlet.jar`
  – `com.ibm.ws.prereq.jaxrs.jar`

  These JAR files are available in the `plugins` directory of Websphere Application Server. Edit the **was.root** property in the supplied *uncompressed_sample_dir*`/scripts/build.properties` file, and point it to your *app_server_root* directory. If you have copied the jars to another location, modify the **was.root** property to point to this location.
- Run the following ant command from the *uncompressed_sample_dir* directory:

  *path_to_ant* `-propertyfile scripts/build.properties -buildfile build.xml`

  The newly-built binary (EBA file) is in the *uncompressed_sample_dir*`/output` directory.

  **Note:** This is the only location to which this EBA file is written. The script does not overwrite the original binary located in the *uncompressed_sample_dir*`/installableApps` directory.

Remove the blabber sample.

To remove the blabber sample, you complete the following 3 steps:

1. Remove the application configuration and the data sources, either by using a script (the first optional step below), or by using the administrative console (the second optional step below).
2. Remove the shared logging bundles from the internal bundle repository.
3. Remove the database.

**Note:** Only remove the bundles if you have no other applications installed that use them. Both the blabber and blog sample applications use the shared logging bundles, so if both applications are installed these bundles should not be removed.

The uninstall script is provided in the `scripts` directory of the `OSGi_blabberSample.zip` compressed archive file. The `blabberSampleUninstall.py` script contains the required jython to remove data sources and to remove the installation of the blabber sample with default configuration. You should fully qualify the path to the script if you do not run it from the directory that contains the script.

In the following steps you must substitute your own values for the variables *app_server_root*, and *profileName*.

- Optional: Remove the application configuration and the data sources by running the following command.

  **Note:** The target application server must be running before you use this script.

  On UNIX platforms:

  ```
  app_server_root/profiles/profileName/bin/wsadmin.sh
            -f scripts/blabberSampleUninstall.py
  ```

  On Windows platforms:

  ```
  app_server_root\profiles\profileName\bin\wsadmin.bat
            -f scripts\blabberSampleUninstall.py
  ```

- Optional: Remove the application configuration and the data sources by using the administrative console.
  1. Remove the application configuration.
     a. Navigate to **Applications** > **Application types** > **Business-level applications**.
     b. Select the business-level application representing the blabber sample application, then click **Stop**.
     c. Click the business-level application representing the blabber sample application to view the configuration details.
     d. Select all the deployed assets, then click **Delete**.
     e. Click **OK** to confirm removal.
     f. Click **Save**.
     g. Select the business-level application representing the blabber sample application, then click **Delete**.
     h. Navigate to **Applications** > **Application types** > **Assets**.
     i. Select the `com.ibm.samples.websphere.osgi.blabber.app.eba` asset, then click **Delete**.
     j. Click **OK** to confirm removal.
     k. Click **Save**.
  2. Remove the data sources.
     a. Navigate to **Resources** > **JDBC** > **Data sources**.
     b. Select the two data sources configured for the blabber application.
     c. Click **Delete**.
     d. Click **Save**.
- Remove the shared logging bundles from the internal bundle repository by using the administrative console.

1. Navigate to **Environment** > **OSGi bundle repositories** > **Internal bundle repository**.
2. Select the following bundles:
   - com.ibm.samples.websphere.osgi.logging.api.jar
   - com.ibm.samples.websphere.osgi.logging.impl.jar
3. Click **Delete**.
4. Click **Save**.

- Remove the database.

  On UNIX platforms, open a command prompt, then enter the following command:

  ```
  cd app_server_root/derby
  rm -fr BLABBERDB
  ```

  On Windows platforms, delete the *app_server_root*\derby\BLABBERDB directory.

# Chapter 23. Developing Portlet applications

This page provides a starting point for finding information about portlet applications, which are special reusable Java servlets that appear as defined regions on portal pages. Portlets provide access to many different applications, services, and web content.

## Portlet aggregation and preferences

## Supported optional features of the JSR-286 Portlet Specification

The simple portal framework, which builds on top of the portlet container, is JSR-286-compliant. However, the WebSphere Application Server implementation supports a subset of the optional features in the JSR-286 Portlet Specification.

The following table lists the optional features that are available in the JSR-286 Portlet Specification and indicates to what extent these optional features are available in WebSphere Application Server.

*Table 131. Optional features in the JSR-286 Portlet Specification. The Availability column states whether the product supports a specification feature.*

| Feature | Availability |
|---|---|
| Container runtime options | The following container runtime options are supported:<br>• javax.portlet.escapeXml<br>• javax.portlet.servletDefaultSessionScope<br>• javax.portlet.actionScopedRequestAttributes |
| Setting the HTML head section elements using the MimeResponse.MARKUP_HEAD_ELEMENT property | This property is not supported as its setting does not have an effect. |
| Custom portlet modes and custom window states | The feature is supported, but without special treatment. |
| Portlet-managed modes | This feature is fully supported. |
| Dynamically setting the portlet title using the RenderResponse.setTitle(String) method | This feature is partially supported. You need to make use of this feature in a portlet document filter or an aggregation JavaServer Pages (JSP) file. |
| Dynamically setting the next possible portlet modes using the RenderResponse.setNextPossiblePortletModes(Collection<PortletMode>) method | This feature is not supported. |
| Expiration and validation-based caching | This feature is fully supported. You need to activate the portlet fragment caching and a cachespec.xml defined as a prerequisite. |
| Aliases in public render parameters | The aliases in public render parameters are supported in the PortletServingServlet servlet and the aggregation tag library. |
| Aliases and wild cards in eventing | These aliases and wild cards are not supported as setting these functions does not have an effect. |

### Aggregation tag library attributes

The aggregation tag library is used to aggregate multiple portlets on one page. This topic describes the attributes within the aggregation tag library.

Supported arguments include:

**`init`**

This tag initializes the portlet framework and has to be used in the beginning of the JSP. All other tags described in this section are only valid in the body of this tag, therefore the init tag usually encloses the whole body of a JSP. In case the current URL contains an action flag the action method of the corresponding portlet is called. The state and insert tags are sub-tags of the init tag.

The init tag has the following attributes:

- portletURLPrefix = ”<any string>”

© Copyright IBM Corp. 2011

This URL defines the prefix used for PortletURLs. Portlet URLs are created either by the state tag or within a portlet's render method, which is called by using the insert tag. This is a required attribute.

- portletURLSuffix = ”<any string>”

  This URL defines the suffix used for PortletURLs. Portlet URLs are created either by the state tag or within a portlet's render method, which is called by using the insert tag. This is attribute optional.

- portletURLQueryParams = ”<any string>”

  This URL defines the query parameters used for PortletURLs. Portlet URLs are created either by the state tag or within a portlet's render method, which is called by using the insert tag. This is attribute optional.

**scope, portlet**

The scope tag and portlet tag are used to provide information that is necessary when a portlet application is installed under a multiple part context root, for example, /context1/context2. These tags also define which portlet windows should participate in portlet coordination via public render parameters, and add a render parameter to the newly created URL.

The urlParam tag has the following attributes:

- context = "/<context1>/<context2>"

  Specifies the context root of the portlet application in which the portlet is deployed. This attribute is required.

- portletname = "<portlet-name>"

  Specifies the portlet-name. This attribute is required.

- windowId = ”<any string>”

  Defines the window ID for the concrete portlet instance. This attribute is required.

The following is an example of how to use the scope and portlet tags:

```
<%@ taglib uri="http://ibm.com/portlet/aggregation" prefix="portlet" %>

<portlet:scope>
    <portlet:portlet context="/myportletcontext1/myportletcontext2" portletname="MyPortlet" windowId="sample"/>
</portlet:scope>

<portlet:init portletURLPrefix="/myportalcontext/ ">
....
</portlet:init>
```

**state**

The state tag creates a URL pointing to the given portlet using the given state. You can place this URL either into a variable specified by the var attribute or you can write it directly to the output stream. This tag is useful to create URLs for HTML buttons, images, and other items such that when the URL is invoked, the state changes defined in the URL are applied to the given portlet.

The state tag has the following attributes:

- url = ”<context>/<portlet-name>”

  Identifies the portlet for this tag by using the context and portlet-name to address the portlet. This attribute is required.

- windowId = ”<any string>”

  Defines the window ID for the portlet URL created by this tag. This is attribute optional.

- var = ”<any string>”

  If defined the URL is written into a variable with the given scope and name, not to the output stream. This is attribute optional.

- scope = ”page|request|session|application”

  This attribute is only valid if the var attribute is specified. If defined, the URL is not written to the output stream but a variable is created in the given scope with the given name. The default is page. This is attribute optional.

- portletMode = ”view|help|edit|<custom>”

  This attribute sets the portlet mode.
- portletWindowState = ”maximized|minimized|normal|<custom>”

  This attribute sets the window state.
- action = ”true/false”

  This attribute defines whether this is an action URL. This is attribute optional. The default is false.

**urlParam**

Adds a render parameter to the newly created URL.

The urlParam tag has the following attributes:

- name = ”<any string>”

  Indicates the name of the parameter. This is attribute required.
- value = ”<any string>”

  Indicates the value of the parameter. This is attribute required.

**insert**

This tag calls the render method of the portlet and retrieves the content as well as the title. You can optionally place the content and title of the specified portlet into variables using the contentVar and titleVar attributes.

The insert tag has the following attributes:

- url = ”<context>/<portlet-name>” (mandatory) Identifies the portlet for this tag by using the context and portlet-name to address the portlet

  This is attribute required.
- windowId = ”<any string>”

  Defines the window ID of the portlet. This is attribute optional.
- contentVar = ”<any string>”

  If defined, the portlet's content is not written to the output stream but written into a variable with the given scope and name. This is attribute optional.
- contentScope = ”page|request|session|application”

  This attribute is only valid if the contentVar tag is used. If defined, the portlet's content is written into a variable with the given scope and name, not to the output stream. The default is page. This is attribute optional.
- titleVar = ”<any string>”

  If defined the portlet's title is written into a variable with the given scope and name. If it is not defined, the title is ignored and not written to the output stream. This is attribute optional.
- titleScope = ”page|request|session|application”

  This attribute is only valid if titleVar tag is used. If defined, the portlet's title is written into a variable with the given scope and name, not to the output stream. The default is page. This is attribute optional.

## Example: Using the portlet aggregation tag library

You can use the aggregation tag library to aggregate multiple portlets to have multiple and different content on one page. The library can be used by every JavaServer Pages (JSP) file that has been included by a servlet.

To use the portlet aggregation tag library, you must declare the tag-lib at the top of the JSP file using, `<%@ taglib uri="http://ibm.com/portlet/aggregation" prefix="portlet" %>`, as in the following example. The following JSP file example shows how to aggregate portlets on one page.

```
<%@ taglib uri="http://ibm.com/portlet/aggregation" prefix="portlet" %>
<%@ page isELIgnored="false" import="java.util.Enumeration"%>

<portlet:init portletURLPrefix="/dummy/portletTagTest/" portletURLSuffix="/more" portletURLQueryParams="p1=v1&p2=v2">
```

```
   <portlet:insert url="worldclock/StdWorldClock" contentVar="worldclockcontent" titleVar="worldclocktitle"/>
    <portlet:state url="worldclock/StdWorldClock" portletMode="view" var="worldclockview"
       portletWindowState="maximized">
        <portlet:urlParam name="namea" value="valuea"/>
        <portlet:urlParam name="nameb" value="valueb"/>
    </portlet:state>
    <portlet:state url="worldclock/StdWorldClock" portletMode="edit" var="worldclockedit" portletWindowState="normal">
        <portlet:urlParam name="name1" value="value1"/>
        <portlet:urlParam name="name2" value="value2"/>
    </portlet:state>
    <portlet:state url="worldclock/StdWorldClock" portletMode="view" var="worldclockmin"
       portletWindowState="minimized">
        <portlet:urlParam name="namemin" value="valuemin"/>
        <portlet:urlParam name="namemin" value="valuemin"/>
    </portlet:state>

    <portlet:insert url="worldclock/StdWorldClock" windowId="min" contentVar="simplecontent" titleVar="simpletitle"/>
    <portlet:state url="worldclock/StdWorldClock" windowId="min" portletMode="view" var="simpleview"
  portletWindowState="maximized">
        <portlet:urlParam name="name3" value="value3"/>
        <portlet:urlParam name="name4" value="value4"/>
        <portlet:urlParam name="name5" value="value5"/>
        <portlet:urlParam name="name5" value="value5a"/>
        <portlet:urlParam name="name5" value="value5b"/>
        <portlet:urlParam name="name5" value="value5c"/>
    </portlet:state>
    <portlet:state url="worldclock/StdWorldClock" windowId="min" portletMode="edit" var="simpleedit"
  action="true" portletWindowState="normal">
        <portlet:urlParam name="name6" value="value6"/>
        <portlet:urlParam name="name6" value="value6z"/>
            </portlet:state>
    <portlet:state url="worldclock/StdWorldClock" windowId="min" portletMode="view" var="simplemin"
  portletWindowState="minimized">
        <portlet:urlParam name="name1" value="value1"/>
        <portlet:urlParam name="name2" value="value2"/>
    </portlet:state>

    <portlet:insert url="test/TestPortlet1" contentVar="testcontent" titleVar="testtitle"/>
    <portlet:state url="test/TestPortlet1" portletMode="view" var="testview" portletWindowState="maximized"/>
    <portlet:state url="test/TestPortlet1" portletMode="edit" var="testedit" portletWindowState="maximized"/>

<!--  This table is the outtermost table for creating two-column portal layout  -->
<TABLE border="0" CELLPADDING="3" CELLSPACING="8" WIDTH="100%">
<TR>
<TD VALIGN="top">

    border-bottom: gray 1px solid;
    border-right: gray 1px solid;
}
.portletBody {
    font-family:Verdana,sans-serif; font-size:70%
}

</STYLE>
```

## Portlet aggregation using JavaServer Pages

The aggregation tag library generates a portlet aggregation framework to address one or more portlets on one page If you write JavaServer Pages, you can aggregate multiple portlets on one page using the aggregation tag library. This tag library does not provide full featured portal aggregation implementation, but provides a good migration scenario if you already have aggregating servlets and JavaServer Pages and want to switch to portlets.

To allow the customer to create a simple portal aggregation, the aggregation tag library also provides the following features.

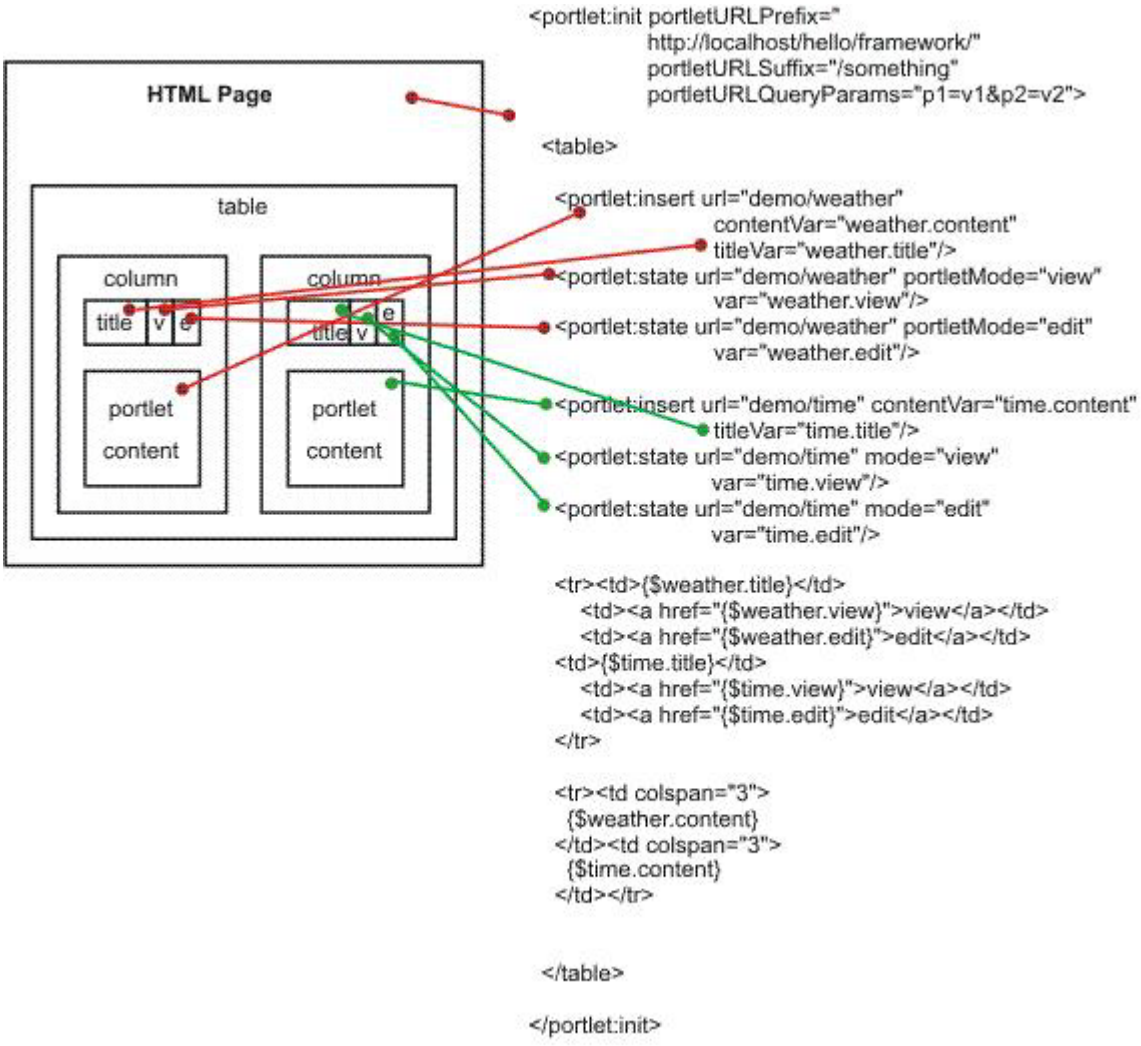
- Invoke a portlet's action method
- Render multiple portlets on one page
- Provide links to change the portlet's mode or window state

- Display the portlet's title
- Retain the portlet cookie state

The aggregation tag library and JavaServer Pages that use the aggregation tag library will only work with the WebSphere Application Server portlet container implementation because the protocol between the tags and the container is not standardized.

Refer to the Aggregation tag library attributes article for information on the aggregation tag library attributes.

The following diagram depicts how an HTML page would look like and what tags are used in order to create the page. Refer to the Aggregation tag library attributes article for information on the aggregation tag library attributes.



When you use the aggregation tag library, you must set the portletUrlPrefix attribute of the init tag to the aggregating application. You need to:

- Ensure that the portletUrlPrefix attribute is set to the following in the aggregator page.

  `"http://" + <server_address> + ":" + <server_port> + "/" + <aggregator context> + "/" <aggregator mapping>`
- Reference the aggregation JSP page within the `web.xml` file through a servlet mapping ending with `/*`. For example, `/aggregation/*`

When aggregating multiple portlets on a single page, special care must be used with the naming conventions of form attribute names in your portlets. Because your portlets are all on the same page, they all share the same HttpServletRequest. When one portlet is viewed the entire page is refreshed and form data is re-posted. Therefore, if there are multiple portlets that are aggregated on a single page with the same form attribute names, there could be logic corruption when form data is re-posted.

## Aggregation tag library attributes

The aggregation tag library is used to aggregate multiple portlets on one page. This topic describes the attributes within the aggregation tag library.

Supported arguments include:

**init**

This tag initializes the portlet framework and has to be used in the beginning of the JSP. All other tags described in this section are only valid in the body of this tag, therefore the init tag usually encloses the whole body of a JSP. In case the current URL contains an action flag the action method of the corresponding portlet is called. The state and insert tags are sub-tags of the init tag.

The init tag has the following attributes:

- portletURLPrefix = ”<any string>”

  This URL defines the prefix used for PortletURLs. Portlet URLs are created either by the state tag or within a portlet's render method, which is called by using the insert tag. This is a required attribute.

- portletURLSuffix = ”<any string>”

  This URL defines the suffix used for PortletURLs. Portlet URLs are created either by the state tag or within a portlet's render method, which is called by using the insert tag. This is attribute optional.

- portletURLQueryParams = ”<any string>”

  This URL defines the query parameters used for PortletURLs. Portlet URLs are created either by the state tag or within a portlet's render method, which is called by using the insert tag. This is attribute optional.

**scope, portlet**

The scope tag and portlet tag are used to provide information that is necessary when a portlet application is installed under a multiple part context root, for example, /context1/context2. These tags also define which portlet windows should participate in portlet coordination via public render parameters, and add a render parameter to the newly created URL.

The urlParam tag has the following attributes:

- context = "/<context1>/<context2>"

  Specifies the context root of the portlet application in which the portlet is deployed. This attribute is required.

- portletname = "<portlet-name>"

  Specifies the portlet-name. This attribute is required.

- windowId = ”<any string>”

  Defines the window ID for the concrete portlet instance. This attribute is required.

The following is an example of how to use the scope and portlet tags:

```
<%@ taglib uri="http://ibm.com/portlet/aggregation" prefix="portlet" %>

<portlet:scope>
    <portlet:portlet context="/myportletcontext1/myportletcontext2" portletname="MyPortlet" windowId="sample"/>
</portlet:scope>

<portlet:init portletURLPrefix="/myportalcontext/ ">
....
</portlet:init>
```

**state**

The state tag creates a URL pointing to the given portlet using the given state. You can place this URL either into a variable specified by the var attribute or you can write it directly to the output stream. This tag is useful to create URLs for HTML buttons, images, and other items such that when the URL is invoked, the state changes defined in the URL are applied to the given portlet.

The state tag has the following attributes:

- url = ”<context>/<portlet-name>”

  Identifies the portlet for this tag by using the context and portlet-name to address the portlet. This attribute is required.
- windowId = ”<any string>”

  Defines the window ID for the portlet URL created by this tag. This is attribute optional.
- var = ”<any string>”

  If defined the URL is written into a variable with the given scope and name, not to the output stream. This is attribute optional.
- scope = ”page|request|session|application”

  This attribute is only valid if the var attribute is specified. If defined, the URL is not written to the output stream but a variable is created in the given scope with the given name. The default is page. This is attribute optional.
- portletMode = ”view|help|edit|<custom>”

  This attribute sets the portlet mode.
- portletWindowState = ”maximized|minimized|normal|<custom>”

  This attribute sets the window state.
- action = ”true/false”

  This attribute defines whether this is an action URL. This is attribute optional. The default is false.

**urlParam**

Adds a render parameter to the newly created URL.

The urlParam tag has the following attributes:

- name = ”<any string>”

  Indicates the name of the parameter. This is attribute required.
- value = ”<any string>”

  Indicates the value of the parameter. This is attribute required.

**insert**

This tag calls the render method of the portlet and retrieves the content as well as the title. You can optionally place the content and title of the specified portlet into variables using the contentVar and titleVar attributes.

The insert tag has the following attributes:

- url = ”<context>/<portlet-name>” (mandatory) Identifies the portlet for this tag by using the context and portlet-name to address the portlet

  This is attribute required.
- windowId = ”<any string>”

  Defines the window ID of the portlet. This is attribute optional.
- contentVar = ”<any string>”

  If defined, the portlet's content is not written to the output stream but written into a variable with the given scope and name. This is attribute optional.
- contentScope = ”page|request|session|application”

This attribute is only valid if the contentVar tag is used. If defined, the portlet's content is written into a variable with the given scope and name, not to the output stream. The default is page. This is attribute optional.

- titleVar = ”<any string>”

  If defined the portlet's title is written into a variable with the given scope and name. If it is not defined, the title is ignored and not written to the output stream. This is attribute optional.

- titleScope = ”page|request|session|application”

  This attribute is only valid if titleVar tag is used. If defined, the portlet's title is written into a variable with the given scope and name, not to the output stream. The default is page. This is attribute optional.

## Example: Using the portlet aggregation tag library

You can use the aggregation tag library to aggregate multiple portlets to have multiple and different content on one page. The library can be used by every JavaServer Pages (JSP) file that has been included by a servlet.

To use the portlet aggregation tag library, you must declare the tag-lib at the top of the JSP file using, `<%@ taglib uri="http://ibm.com/portlet/aggregation" prefix="portlet" %>`, as in the following example. The following JSP file example shows how to aggregate portlets on one page.

```
<%@ taglib uri="http://ibm.com/portlet/aggregation" prefix="portlet" %>
<%@ page isELIgnored="false" import="java.util.Enumeration"%>

<portlet:init portletURLPrefix="/dummy/portletTagTest/" portletURLSuffix="/more" portletURLQueryParams="p1=v1&p2=v2">

   <portlet:insert url="worldclock/StdWorldClock" contentVar="worldclockcontent" titleVar="worldclocktitle"/>
    <portlet:state url="worldclock/StdWorldClock" portletMode="view" var="worldclockview"
       portletWindowState="maximized">
        <portlet:urlParam name="namea" value="valuea"/>
        <portlet:urlParam name="nameb" value="valueb"/>
    </portlet:state>
    <portlet:state url="worldclock/StdWorldClock" portletMode="edit" var="worldclockedit" portletWindowState="normal">
        <portlet:urlParam name="name1" value="value1"/>
        <portlet:urlParam name="name2" value="value2"/>
    </portlet:state>
    <portlet:state url="worldclock/StdWorldClock" portletMode="view" var="worldclockmin"
       portletWindowState="minimized">
        <portlet:urlParam name="namemin" value="valuemin"/>
        <portlet:urlParam name="namemin" value="valuemin"/>
    </portlet:state>

    <portlet:insert url="worldclock/StdWorldClock" windowId="min" contentVar="simplecontent" titleVar="simpletitle"/>
    <portlet:state url="worldclock/StdWorldClock" windowId="min" portletMode="view" var="simpleview"
  portletWindowState="maximized">
        <portlet:urlParam name="name3" value="value3"/>
        <portlet:urlParam name="name4" value="value4"/>
        <portlet:urlParam name="name5" value="value5"/>
        <portlet:urlParam name="name5" value="value5a"/>
        <portlet:urlParam name="name5" value="value5b"/>
        <portlet:urlParam name="name5" value="value5c"/>
    </portlet:state>
    <portlet:state url="worldclock/StdWorldClock" windowId="min" portletMode="edit" var="simpleedit"
  action="true" portletWindowState="normal">
        <portlet:urlParam name="name6" value="value6"/>
        <portlet:urlParam name="name6" value="value6z"/>
            </portlet:state>
    <portlet:state url="worldclock/StdWorldClock" windowId="min" portletMode="view" var="simplemin"
  portletWindowState="minimized">
        <portlet:urlParam name="name1" value="value1"/>
        <portlet:urlParam name="name2" value="value2"/>
    </portlet:state>

    <portlet:insert url="test/TestPortlet1" contentVar="testcontent" titleVar="testtitle"/>
    <portlet:state url="test/TestPortlet1" portletMode="view" var="testview" portletWindowState="maximized"/>
    <portlet:state url="test/TestPortlet1" portletMode="edit" var="testedit" portletWindowState="maximized"/>

    <tr>
    <td CLASS="portletBody" COLSPAN="2">
      ${simplecontent}
     </td>
    </tr>
  </table>

    </TD>
    </TR>
    </table>

</portlet:init>
```

You can include the following formatting to the previous example JSP file immediately after declaring the tag library.

```
<STYLE TYPE="TEXT/CSS">
BODY {
    font-family:Verdana,sans-serif; font-size:70%
}
.portletTitle {
    text-align: left;border-top: #000000 1px solid; border-bottom: #000000 1px solid; FONT-SIZE: 60.0%;
    COLOR: #ffffff; FONT-FAMILY: Verdana, Arial, Helvetica, sans-serif; BACKGROUND-COLOR: #5495d5;
}
.portletTitleControls {
    text-align: right;border-top: #000000 1px solid; border-right: #000000 1px solid; border-bottom: #000000
    1px solid; FONT-SIZE: 60.0%; COLOR: #ffffff; FONT-FAMILY: Verdana, Arial, Helvetica, sans-serif;
    BACKGROUND-COLOR: #5495d5;
}
.portletTitleControls A {
    COLOR: #ffffff; text-decoration:none; border:#5495d5 1px solid;border-left:white 1px solid;
    padding-left:0.5em; padding-right:0.5em;
}
.portletTitleControls A:hover {
    COLOR: #ffffff; text-decoration:none; border-top:white 1px solid;
   border-bottom:white 1px solid;border-right:white 1px solid;
}
.minimizeControl {
```

```
    font-weight:bold; font-size:100%;
}
.portletTable {
    border-left: gray 1px solid;
    border-bottom: gray 1px solid;
    border-right: gray 1px solid;
}
.portletBody {
    font-family:Verdana,sans-serif; font-size:70%
}

</STYLE>
```

# Portlet preferences

Preferences are set by portlets to store customized information. By default, the PortletServingServlet servlet stores the portlet preferences for each portlet window in a cookie. However, you can change the location to store them in either a session, an `.xml` file, or a database.

## Storing portlet preferences in cookies

The attributes of the cookie are defined as follows:

**Path**
*context/portlet-name/portletwindow*

**Name:**
The name of the cookie has the fixed value of **PortletPreferenceCookie**.

**Value**
The value of the cookie contains a list of preferences by mapping to the following structure:

*['/' pref-name *['=' pref-value]]

All preferences start with '/' followed by the name of the preference. If the preference has one or more values, the values follow the name separated by the '=' character. A null value is represented by the string '#*!0_NULL_0!*#'. As an example, the cookie value may look like, `/locations=raleigh=boeblingen/regions=nc=bw`

## Customizing the portlet preferences storage

You can override how the cookie is handled to store preferences in a session, an `.xml` file or database. To customize the storage, you must create a filter, servlet or JavaServer Pages file as new entry point that wraps the request and response before calling the portlet. Examine the following example wrappers to understand how to change the behavior of the PortletServingServlet to store the preferences in a session instead of cookies.

The following is an example of how the main servlet manages the portlet invocation.

```
public class DispatchServlet extends HttpServlet
{
    ...
  public void service(HttpServletRequest request, HttpServletResponse response)
  throws ServletException, IOException
  {
 response.setContentType("text/html");

 // create wrappers to change preference storage
 RequestProxy req = new RequestProxy(request);
 ResponseProxy resp = new ResponseProxy(request, response);

 // create url prefix to always return to this servlet
                ...
                req.setAttribute("com.ibm.wsspi.portlet.url.prefix", urlPrefix);

 // prepare portlet url
 String portletPath = request.getPathInfo();
```

```
                ...

 // include portlet using wrappers
 RequestDispatcher rd = getServletContext().getRequestDispatcher(modifiedPortletPath);
                rd.include(req, resp);
  }
}
```

In the following example, the request wrapper changes the cookie handling to retrieve the preferences out of the session.

```
public class RequestWrapper extends HttpServletRequestWrapper
{
    ...
    public Cookie[] getCookies() {
        Cookie[] cookies = (Cookie[]) session.getAttribute("SessionPreferences");
        return cookies;
    }
}
```

In the following example, the response wrapper changes the cookie handling to store the preferences in the session:

```
public class ResponseProxy extends HttpServletResponseWrapper
{
   ...
    public void addCookie(Cookie cookie) {
        Cookie[] oldCookies = (Cookie[]) session.getAttribute("SessionPreferences");
        int newPos = (oldCookies == null) ? 0 : oldCookies.length;
        Cookie[] newCookies = new Cookie[newPos+1];
        session.setAttribute("SessionPreferences", newCookies);

        if (oldCookies != null) {
        System.arraycopy(oldCookies, 0, newCookies, 0, oldCookies.length);
        }
        newCookies[newPos] = cookie;
    }
}
```

## Portlet coordination

You can use either the events mechanism or the public render parameters mechanism to coordinate portlets within a portal.

JSR 286 defines these two mechanisms as follows:

- Events: Loose-coupling of portlets during action phase.
- Public render parameters: Sharing of view state between portlets.

The WebSphere Application Server portlet container supports both concepts with one exception. The wiring of events on a portal level is not supported.

To make use of the public render parameters on a portal page defined with the aggregation tag library, you must explicitly declare the portal scope:

```
<%@ taglib uri="http://ibm.com/portlet/aggregation" prefix="portlet" %>
<%@ page isELIgnored ="false"%>

<!-- define portal scope for public render parameters -->
<portlet:scope>
  <portlet:portlet context="/simpleportlet" portletname="SimplePortlet1" windowId="id1"/
  <portlet:portlet context="/simpleportlet2" portletname="SimplePortlet2" windowId="id2"/>
</portlet:scope>

<portlet:init portletURLPrefix="/my-webapp-context/my-portal-jsp-url-pattern/">
<!-- insert your portlets here, wrapped with your html markup -->
...
   <portlet:insert url="simpleportlet/SimplePortlet1" windowId="id1" titleVar="portlettitle_1"/>
```

```
...
   <portlet:insert url="simpleportlet2/SimplePortlet2" windowId="id2" titleVar="portlettitle_1"/>
...
</portlet:init>
```

The public render parameters are only visible to the portlet windows mentioned within this defined scope. This condition assumes, as a prerequisite, that the corresponding portlets have also declared support for a given public render parameter in their portlet.xml file, according to the JSR 286 specification:

```
...
   <portlet>
      <portlet-name>portlet_name1</portlet-name>
       ...
       <supported-public-render-parameter>foo</supported-public-render-parameter>
   </portlet>
   <portlet>
      <portlet-name>portlet_name2</portlet-name>
       ...
       <supported-public-render-parameter>foo</supported-public-render-parameter>
   </portlet>
   <public-render-parameter>
       <identifier>foo</identifier>
       <qname xmlns:x="http://example.com/params">x:foo2</qname>
   </public-render-parameter>
...
```

# Converting portlet fragments to an HTML document

A portlet only delivers fragment output whereas a servlet typically delivers document output. However, you can use the PortletServingServlet servlet, which is similar to the FileServingServlet servlet, to address portlets like servlets.

## About this task

A default document servlet filter, the DefaultFilter filter, is applied to the PortletServingServlet servlet to return the portlet‘s content inside of a document. This filter only applies to requests, not to includes or forwards using the RequestDispatcher method. A servlet filter that is used to embed the portlet‘s content into a document is called the document servlet filter. You can define additional document servlet filters in a `.xml` file. The FilterRequestHelper attribute within com.ibm.wsspi.portletcontainer.util is provided to assist the document servlet filters in analyzing a request regarding filter chain and portlet information. It is used in supporting dynamic portlet titles, as a marker for redirection for document servlet filters and to ensure that document conversion is completed once.

## Procedure

1. Add a new document servlet filter. The filter capability is a server feature, therefore all filters must be installed into the server to use the filter capability of the server. The filters need to be available in any classes or library directory on a server level. You must also register the filter in a `plugin.xml` file within the root of a Java archive (JAR) file. The following is an example of how to register the filter in a `plugin.xml` file.

   ```
   <?xml version="1.0" encoding="UTF-8"?>
   <?eclipse version="3.0"?>
   <plugin id="sample.plugin" name="Customer_Plugin" provider-name="Customer" version="1.0.0">
     <extension point="com.ibm.ws.portletcontainer.portlet-document-filter-config">
       <portlet-document-filter class-name="sample.filter.CustomFilter" order="200" />
     </extension>
   </plugin>
   ```

2. Optional: Set dynamic portlet titles by providing the dynamic title as a request attribute. The PortletServingServlet servlet supports dynamic portlet titles by providing the dynamic title as a request attribute, FilterRequestHelper.DYNAMIC_TITLE. This attribute returns the dynamic portlet title if it has been set by the portlet, otherwise it returns the static portlet title of the `portlet.xml` file if defined.

DYNAMIC_TITLE = 'javax.portlet.title' The DefaultFilter uses this request attribute to set the document title while converting the fragment into a document. If you want the filter to support browser caching or dynamic portlet titles, you must cache the complete portlet content.

3. Specify cache handling for the portlet rendering call to support dynamic title. Redirection for document servlet filters

   A document servlet filter can set a marker as request attribute, FilterRequestHelper.REDIRECT. This marker ensures that the portlet container returns to the document servlet filter after the portlet action has been called prior to any render calls. You must define the following constants, REDIRECT = 'com.ibm.websphere.portlet.action' and REDIRECT_VALUE = 'redirect'. The DefaultFilter uses this request attribute to provide special cache handling for the portlet rendering call to support dynamic title.

4. Convert the portlet's fragment into a valid document. Document conversion must be completed only once. Therefore each document servlet filter must ensure that the fragment has not yet been converted to a document previously. If the document servlet filter converts the fragment to a document, the request attribute FilterRequestHelper.DOCUMENT must be set to FilterRequestHelper.DOCUMENT_VALUE. This request attribute marks whether the conversion still needs to be completed. The following constants are defined, DOCUMENT = 'com.ibm.websphere.portlet.filter' and DOCUMENT_VALUE = 'document'. The DefaultFilter uses this request attribute to check whether it should convert the fragment to an Hypertext Markup Language (HTML) document. For example, this allows another document servlet filter in front to convert the fragment into a valid Wireless Markup Language (WML) document instead.

# Assembling portlets

## Portlet Uniform Resource Locator (URL) addressability

You can request a portlet directly through a Uniform Resource Locator (URL) to display its content without portal aggregation. The PortletServingServlet servlet registers each web application that contains portlets. It is similar to the FileServingServlet servlet of the web container that serves resources. The PortletServingServlet servlet supports direct rendering of portlets into a full browser page by a URL request.

You can invoke each portlet by its context root and name with the URL mapping /<portlet-name> that is created for each portlet. The context root and name has the following format:

```
http://<host>:<port>/<context-root>/<portlet-name> For example,
 http://localhost:9080/portlets/TestPortlet1
```

The context root identifies the web application archive (WAR) file that contains the portlet. The portlet name uniquely identifies the portlet with a portlet application of a WAR file. The DefaultDocumentFilter servlet only supports HTML, UTF8 encoding and an extended URL form based on the basic URL form as shown above.

You can only display one portlet at a time using the PortletServingServlet servlet. If you want to aggregate multiple portlets on the page, you need to use the aggregation tag library. Refer to the Portlet aggregation using JavaServer Pages article for additional information.

Because a portlet only delivers fragment output whereas a servlet usually delivers document output, a mechanism is introduced to convert the fragment into a document, called the PortletDocumentFilter filter. By default, the PortletDocumentFilter filter only supports converting HTML. The conversion is implemented using a servlet filter before the PortletServingServlet servlet is initiated to return the portlet‘s content inside of a document. This default document servlet filter only applies to URL requests, not for includes or forwards using the RequestDispatcher method. You can create servlet filters to support other markups additional document servlet filters. Refer to the Converting portlet fragments to an HTML document article, for additional information.

The PortletServingServlet servlet does not persist portlet preferences in a XML file or database. It places the portlet preferences directly into a cookie to store the preferences persistently. Refer to the Portlet preferences article, for additional information on how to change this behavior.

## Portlet URL syntax

You can add additional portal context such as portlet mode or window state. You can access the PortletServingServlet servlet by using a URL mapping that has the following structure:

```
http://host:port/context/portlet-name [/portletwindow[/ver [/action |
 /resource[/id=custom-id][/cacheability]] [/mode] [/state] [rparam][/?name]]]
```

Any differing URL structure results in a com.ibm.wsspi.portletcontainer.InvalidURLException exception. Empty strings are not permitted as parameter values and creates an InvalidURLException exception. The following is a list of valid parameters:

**http:// host:port/context/***portlet-name*
: This is the minimum URL required to access a portlet. A default portlet window called ‘default’ is created. The *portlet-name* variable is case-sensitive.

**/***portletwindow*
: This parameter identifies the portlet window. You must set this parameter if you choose to add more portal context information to the URL.

**/ver=***major.minor*
: This optional parameter is used to define the version of the portlet API that is used. You must set this parameter if you choose to add more portal context information to the URL. Only versions '1.0’ and '2.0' are supported. Any other version creates an InvalidURLException exception.

**/action**
: This is a required parameter if you call the action method of the portlet. The action parameter causes the action process of the portlet to be called. After the action has been completed, a redirect is automatically issued to call the render process. To control the subsequent render process, a document servlet filter can set a request attribute with name 'com.ibm.websphere.portlet.action' and value 'redirect' to specify that the portlet serving servlet directly returns after action without calling the render process.

**/mode=view | edit | help |** *custom-mode*
: This optional parameter defines the portlet mode that is used to render the portlet. The default mode is ‘view’. The value is not case-sensitive. For example, ‘View’, ‘view’ or ‘VIEW’ results in the same mode.

**/state=normal | maximized | minimized |** *custom-state*
: This optional parameter defines the window state that is used to render the portlet. The default state is ‘normal’. The value is not case-sensitive, for example, ‘Normal’, ‘normal’, or ‘NORMAL’ results in the same state.

*** [ /rparam=***name* ***[=***value***] ]**
: This optional parameter specifies render parameters for the portlet. Repeat this parameter chain to provide more than one render parameter. For example, /rparam=invitation/ rparam=days=Monday=Tuesday.

**?name=***value***&***name2***=***value2* **...**
: Query parameters may follow optionally. They are not explicitly supported by the portlet container, but they do not invalidate the URL format.

**/action | /resource**
: This parameter defines the methods of the portlet that is called. Valid values are no, action or resource parameter. No specific method defined calls the render method. The resource parameter is only supported for JSR 286 portlets.

**/resource [/id=custom-id] [/cacheability=cacheLevelFull | cacheLevelPortlet | cacheLevelPage]**
Set this parameter to define the method of the portlet to be called. No redirection occurs. No other method of the portlet is called. To control the resource parameter, you can add an additional ID parameter to provide a resource serving identifier that is passed through to the portlet. The cacheability parameter defines the cache level of this resource URL. This parameter is only supported with JSR 286 portlets .

The following list includes examples of valid JSR 168 and JSR 286 URLs:

- http:// localhost:9080/sample/WorldClock
- http:// localhost:9080/sample/WorldClock/myPortlet/ver=1.0/mode=edit/rparam=timezone=UTC
- http:// localhost:9080/sample/WorldClock/myPortlet/ver=1.0/action/state=maximized?timezone=UTC
- http://localhost:9080/sample/WorldClock/myPortlet/ver=2.0/resource/id=somePicture.jpg

## Example: Configuring the extended portlet deployment descriptor to disable PortletServingServlet

Portlet URL serving supports direct access to all functions and states of a portlet by creating the appropriate URLs. In a production setup where the portlet is served through an enterprise portal application that applies its own access control, is considered a security risk. By setting the portletServingEnabled property to false, an administrator can ensure that a sensitive portlet is never accessed by direct URL serving.

Extensions for the portlet deployment descriptor are defined within a file called `ibm-portlet-ext.xmi`. This deployment descriptor is an optional descriptor that you can use to configure WebSphere extensions for the portlet application and its portlets. For example, you can disable the PortletServingServlet servlet for the portlet application in the extended portlet deployment descriptor.

The `ibm-portlet-ext.xmi` extension file is loaded during application startup. If there are no extension files specified with this setting, the default values of the portlet container are used.

The default for the portletServingEnabled attribute is true. The following is an example of how to configure the application so that a PortletServingServlet servlet is not created for any portlet on the portlet application.

```
<?xml version="1.0" encoding="UTF-8"?>
<portletappext:PortletApplicationExtension xmi:version="1.0"
    xmlns:xmi="http://www.omg.org/XMI"
    xmlns:portletappext="portletapplicationext.xmi"
    xmlns:portletapplication="portletapplication.xmi"
    xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xmi:id="PortletApp_ID_Ext"
    portletServingEnabled="false">
  <portletappext:portletApplication href="WEB-INF/portlet.xml#myPortletApp"/>
</portletappext:PortletApplicationExtension>
```

# Chapter 24. Developing SCA composites

This page provides a starting point for finding information about Service Component Architecture (SCA) composites, which consist of components that implement business functions in the form of services.

You typically do not deploy SCA composites directly onto a product server. To deploy SCA composites, you import SCA composites as assets to the product repository and add the assets to business-level applications.

## Selecting the implementation type for an SCA composite

A benefit of Service Component Architecture (SCA) is that you can use existing assets in an application, without having to change the asset implementation. Many enterprises have application assets developed using a variety of technologies and frameworks, including assets previously deployed in a WebSphere Application Server environment, which is predominantly Java Platform, Enterprise Edition (Java EE) or Java-centric. SCA supports several service implementation technologies.

### Before you begin

Determine which application files or artifacts (assets) you want to deploy in an SCA application. If necessary, develop the files or artifacts.

### About this task

You can use SCA composites to:

- Reuse existing service implementations in the definition of an SCA component for use in an SCA composite application.
- Enable the services within those technologies to be exposed or use a service over the supported access bindings without changing the business logic of the service.

Each component within an SCA assembly specifies the implementation technologies which provide the specific business logic which implements the services described in the component definition. A composite is composed of 1-to-many components, each of which can be made up of differing implementation technologies.

SCA supports the following implementation programming model technologies:

**implementation.java**
The implementation conforms to the SCA Java Component Implementation specification.

**implementation.composite**
The implementation conforms to an SCA composite as defined in the SCA Assembly Model specification.

**implementation.web**
The implementation conforms to Java EE 1.5 for Web modules and Web archive (WAR) files.

**implementation.ejb**
The implementation conforms to Java EE 1.5 for Enterprise JavaBeans (EJB) 2.1 and 3.0 Stateless Session Beans.

**implementation.jee**
The implementation conforms to Java EE 1.5 for enterprise archive (EAR) files.

**implementation.osgiapp**
The implementation conforms to the OSGi application programming model as supplied in the product.

© Copyright IBM Corp. 2011

**implementation.spring**
The implementation conforms to the SCA Spring Component Implementation specification.

WebSphere Application Server does not include the Spring 2.5.5 package. You must obtain the Spring 2.5.5 package from the supplying vendor.

**implementation.widget**
The implementation is SCA-enhanced JavaScript contained within an HTML page. Unlike the other implementation types, this component runs on the server but it is returned to browsers from the server. You wire services that JavaScript code references through SCA bindings.

## Procedure

1. Select the implementation type to use for the SCA component.

*Table 132. Supported SCA implementation types. Based on the implementation technology of an asset, select the SCA implementation type to use in the SCA component.*

| Asset implementation technology | SCA implementation type |
|---|---|
| SCA Java | `implementation.java` |
| SCA assembly | `implementation.composite` |
| Java EE application (EAR) | `implementation.jee` |
| Java EE EJB module, session bean, or message-driven bean | `implementation.ejb` |
| Java EE Web module in a Java EE application | `implementation.web` |
| Enterprise bundle archive (EBA) artifact that uses OSGi bundles and Blueprint components | `implementation.osgiapp` |
| Bean that follows the Java 2 Platform, Standard Edition (J2SE) programming model in a Spring 2.5.5 container. | `implementation.spring` |
| HTML page enriched with JavaScript code that contains SCA for return to a browser. An SCA service returns data in JavaScript. The data can be in Atom collections or in JavaScript Object Notation (JSON) format. | `implementation.widget` |

2. Configure the binding for the selected implementation type and use the binding in an SCA component or application.

   See topics in the related links for information on specifying implementations and bindings.

## Results

The SCA composite makes the appropriate environmental transitions to connect the implementation technology to any exposed bindings that are also in the composite definition.

## What to do next

Deploy the SCA composite or application in a business-level application.

# Developing Service Component Architecture (SCA) services

To develop SCA service implementations, you can use either a top-down development approach starting with an existing Web Services Description Language (WSDL) file or you can use a bottom-up development approach starting from an existing Java interface or implementation. When using either the top-down or bottom-up development methodologies, you can develop service clients or use tools to map business exceptions on remotable interfaces.

# Developing SCA services from existing WSDL files

You can develop a Service Component Architecture (SCA) service implementation when starting with an existing Web Services Description Language (WSDL) file.

## Before you begin

Locate the WSDL file that defines the SCA service that you want to implement. You can develop a WSDL file or obtain one from an existing SCA service. The WSDL file describes your service interface as a WSDL portType and includes XSD schema definitions of your business data.

The product supports Web Services Description Language (WSDL) Version 1.1 definitions that also conform to the WS-I Basic Profile Version 1.1 and Simple SOAP Binding Profile 1.0 standards, and use the document literal style. All these conditions are required for support.

## About this task

There are two ways to develop an SCA service implementation:

- Top-down development starting with an existing Web Services Description Language (WSDL)
- Bottom-up development starting from existing Java code that uses Java Architecture for XML Binding (JAXB) data types

The top-down development approach takes advantage of the interoperable XML-based WSDL, and XSD interface and data definitions.

This task describes the steps when using the top-down development approach to develop an SCA service implementation in Java when starting from a WSDL interface and XSD data definitions.

**Note:** It is a best practice to use the top-down methodology to develop SCA service implementations because this approach uses the capabilities of the XML interface description and provides greater ease in interoperability across platforms, bindings, and programming languages.

Use the wsimport command-line tool to generate the Java representations of your business service interfaces and your business data when an existing WSDL file describes the wanted SCA service interface as a WSDL portType, along with XSD schema definitions of your business data. The wsimport tool generates Java classes that you can use to write a Java implementation that reflects your business logic. The result is a Plain Old Java Object (POJO) implementation of the generated interface using the generated JAXB data types. By adding the @Service annotation to the Java implementation, the annotation defines the Java implementation as an SCA service implementation.

The generated annotated Java classes that correspond to your business data contain all the necessary information that the JAXB runtime environment requires to build and parse the XML for marshaling and unmarshaling. In other words, the data programming model is limited to object instantiation and the use of getter and setter methods, and you do not need to write code to convert the data between the XML wire format and the Java application.

**Note:** The product uses XML marshaling as defined by JAXB to marshal and unmarshal data across a remotable interface. If you start with a remotable Java interface for your implementation rather than starting with a WSDL portType interface, be careful when selecting the input and output Java data types and ensure that you understand which data is preserved across JAXB marshaling and unmarshalling. However, when authoring an implementation on a local interface, you can use any Java type because local interfaces use pass-by-reference semantics, which implies no data is copied.

**Note:** The product does not support using a WSDL file when the Java mapping requires holder classes. The product uses the JAX-WS specification to define the mapping between WSDL files and Java,

including the mapping between a WSDL portType object and a Java interface. When you have WSDL portType objects with operations that use in-out parameters or operations that use multiple output parameters, the JAX-WS specification uses instances of the javax.xml.ws.Holder class in the mapping of the WSDL portType object to a Java interface. When using the product, do not use a WSDL file when the Java mapping requires holder classes. Instead, use a WSDL file that does not map to holder classes.

When you develop an SCA service when starting from an existing WSDL file, the interface is considered a remotable interface. The remotable interface uses pass-by-value semantics, which implies your data is copied.

You can use and deploy the resulting Java implementation as an SCA component that is defined in a composite definition. The composite definition defines SCA artifacts, such as service references, imports, and exports. The component is defined in terms of development artifacts such as the WSDL, the Java implementation, and bindings that are defined during deployment.

The JAXB APIs require that you register Java class types that you want to marshal or unmarshall with a JAXBContext class. The product runtime environment registers these Java class types for you by introspecting your Java interface. When this introspection occurs, be careful of possible problems when polymorphism (inheritance) is used. When an interface is defined in terms of a base superclass type, and you want to pass argument instances of a derived subclass type at run time, the subclasses are not known to the JAXBContext class by simply introspecting the interface parameter types.

In JAXB, you can use the javax.xml.bind.annotation.XmlSeeAlso annotation to solve this problem with polymorphism. Place the @XmlSeeAlso annotation on the generated Java interface that is generated with the @WebService annotation, to refer to additional JAXB derived subclass classes that are added to the JAXBContext class along with those classes introspected from the interface parameters.

## Procedure

1. Use the wsimport command-line tool to develop SCA Java representations of your business service interfaces and your business data.

   The wsimport tool processes a WSDL file and generates Java classes and the JAXB data types that are used to create the SCA service.

   It is important to include all generated classes within your application archive, including the classes that you might not directly reference in your Java implementation. Even if you have simple interfaces that pass simple parameter types like String and Integer, or where no JAXB data types are necessary, be sure to include all classes, including indirect references, in this code generation step.

   - Run the wsimport command to generate the artifacts.

   The wsimport tool is located in the *app_server_root*/bin/ directory.

   Windows

   *app_server_root*\bin**wsimport.bat -keep *wsdl_URL***

   AIX HP-UX Linux Solaris

   *app_server_root*/bin/**wsimport.sh -keep *wsdl_URL***

   The **-keep** option specifies to keep the generated Java source files and the compiled class files.
2. Locate the Java interface that directly corresponds to your WSDL portType from the generated artifacts. The interface is generated with an @WebService annotation, and it is an interface and not a class file.
3. Complete the implementation of your SCA service. Write a Java implementation of the generated Java interface that reflects your business logic. The Java implementation is a Plain Old Java Object (POJO) implementation of the generated interface using the generated JAXB data types. This implementation is annotated based on the SCA Java component implementation programming model.

4. Annotate the Java implementation. Add the @Service annotation to the Java implementation to specify this implementation is an SCA service. When you complete this step, you have created an SCA component implementation.
5. Define a component within a composite definition using this component implementation. In the definition of your composite, define a component that refers to the original WSDL portType interface and the SCA implementation.
   a. Under the <component> element, create a <implementation.java> child element that refers to the class name of your POJO component implementation.
   b. Under the <component> element, create a <service> child element.
   c. Under the <service> element, create a <interface.wsdl ..> element that refers to the WSDL portType. The @name attribute of the <service> element must match the unqualified class name of your Java interface.

   You now have a component with a well-defined component name and service name with a well-defined interface.

   In addition to these aspects of your component definition described by these development procedures, there are other aspects of defining a component. These aspects include adding bindings, configuring property values, defining intents, attaching policy sets, and resolving references. You can create multiple components using this same implementation, but all component definitions are the same with respect to the <implementation.java>, <interface.wsdl> and <service> elements described in this step.
6. Deploy the SCA service by creating the SCA business level application from a deployable composite.

   In the previous step, you defined a component providing your SCA service within a composite definition. This composite is either a deployable composite, or one that is used recursively as a composite implementation of a component in a higher-level composite. To learn how to deploy the SCA service, read about deploying and administering business-level applications.

## Results

You have created an SCA implementation by starting with an existing WSDL file.

## Example

The following example illustrates using an existing WSDL interface to generate a Java interface that is used to create a Java implementation that is an SCA service.

1. Copy the following sample account.wsdl WSDL file to a temporary directory.

```
<?xml version="1.0" encoding="UTF-8"?>

<wsdl:definitions xmlns:soap="http://schemas.xmlsoap.org/wsdl/soap/"
     xmlns:wsdl="http://schemas.xmlsoap.org/wsdl/"
     xmlns:account="http://www.myaccount.com/account"
     targetNamespace="http://www.myaccount.com/account"
     name="AccountService">

      <wsdl:types>
         <schema targetNamespace="http://www.myaccount.com/account"
             xmlns="http://www.w3.org/2001/XMLSchema"
             xmlns:xsd="http://www.w3.org/2001/XMLSchema"
             xmlns:account="http://www.myaccount.com/account">

               <element name="computeAccountAverage">
                 <complexType>
                     <sequence>
                         <element name="account" type="account:Account" />
                         <element name="days" type="xsd:int" />
                     </sequence>
                 </complexType>
             </element>
             <element name="computeAccountAverageResponse">
                 <complexType>
```

```
                    <sequence>
                        <element name="return" type="xsd:float" />
                    </sequence>
                </complexType>
            </element>

            <complexType name="Account">
                <attribute name="accountNumber" type="xsd:int" />
                <attribute name="accountID" type="xsd:string" />
                <attribute name="accountType" type="xsd:string" />
                <attribute name="balance" type="xsd:float" />
            </complexType>

         </schema>
    </wsdl:types>

    <wsdl:message name="computeAccountAverageRequest">
        <wsdl:part element="account:computeAccountAverage"
            name="parameters" />
    </wsdl:message>

    <wsdl:message name="computeAccountAverageResponse">
        <wsdl:part element="account:computeAccountAverageResponse"
            name="parameters" />
    </wsdl:message>

    <wsdl:portType name="AccountService">
        <wsdl:operation name="computeAccountAverage">
            <wsdl:input message="account:computeAccountAverageRequest" name="accountReq"/>
            <wsdl:output message="account:computeAccountAverageResponse" name="accountResp"/>
        </wsdl:operation>
    </wsdl:portType>

    <wsdl:binding name="AccountServiceSOAP" type="account:AccountService">
        <soap:binding style="document"
            transport="http://schemas.xmlsoap.org/soap/http" />
        <wsdl:operation name="computeAccountAverage">
           <soap:operation
                soapAction="computeAccountAverage" />
            <wsdl:input name="accountReq">
               <soap:body use="literal" />
            </wsdl:input>
            <wsdl:output name="accountResp">
                <soap:body use="literal" />
            </wsdl:output>
        </wsdl:operation>

     </wsdl:binding>

    <wsdl:service name="AccountWSDLService">
        <wsdl:port binding="account:AccountServiceSOAP"
            name="AccountServicePort">
            <soap:address location=""/>
        </wsdl:port>
    </wsdl:service>
</wsdl:definitions>
```

2. Run the wsimport command from the *app_server_root*/bin/ directory.

   Windows

   ```
   app_server_root\bin\wsimport.bat -keep -verbose account.wsdl
   ```

   Linux AIX HP-UX Solaris Run the wsimport command,

   ```
   app_server_root/bin/wsimport.sh -keep -verbose account.wsdl
   ```

   After generating the template files using the wsimport command, the following Java files are generated:

   ```
   com/myaccount/account/Account.java
   com/myaccount/account/AccountService.java
   com/myaccount/account/AccountWSDLService.java
   ```

```
com/myaccount/account/ComputeAccountAverage.java
com/myaccount/account/ComputeAccountAverageResponse.java
com/myaccount/account/ObjectFactory.java
com/myaccount/account/package-info.java
```

3. Identify the generated Java interface from the generated classes.

```
//
// Generated By:JAX-WS RI IBM 2.1.1 in JDK 6 (JAXB RI IBM JAXB 2.1.3 in JDK 1.6)
//
package com.myaccount.account;
...
@WebService(name = "AccountService", targetNamespace = "http://www.myaccount.com/account")
...
public interface AccountService {
    /**
     *
     * @param days
     * @param account
     * @return
     *     returns float
     */
    @WebMethod(action = "computeAccountAverage")
    @WebResult(targetNamespace = "")
    @RequestWrapper(localName = "computeAccountAverage", targetNamespace = "http://www.myaccount.com/account",
            className = "com.myaccount.account.ComputeAccountAverage")

    @ResponseWrapper(localName = "computeAccountAverageResponse", targetNamespace = "http://www.myaccount.com/account",
            className = "com.myaccount.account.ComputeAccountAverageResponse")
    public float computeAccountAverage(
        @WebParam(name = "account", targetNamespace = "")
        Account account,
        @WebParam(name = "days", targetNamespace = "")
        int days);

}
```

This code example is a Java interface, not merely a Java class. The @WebService annotation is present in this Java interface. It is important to know that this example is not the same as the generated @WebServiceClient class, com.myaccount.account.AccountWSDLService, which is not an interface and is not needed in your SCA application.

4. Complete the implementation of your SCA service by writing a Java implementation of this generated Java interface. Be sure to add the SCA @Service annotation to the implementation.

```
package com.myaccount.account;
import org.osoa.sca.annotations.Service;
@Service(AccountService.class)
public class AccountServiceImpl implements AccountService
    public float computeAccountAverage( Account account, int days) {

        // Write your business logic here.  Account is a
        // generated JAXB type and so use the JAXB programming model.
        // For example, object instantation is performed using
        // the ObjectFactory.createAccount()) method.
    }
}
```

By completing this step, you have completed a component implementation. Not only is this component implementation a Java implementation of a Java interface, but the @Service annotation signifies that this is a Java component implementation of an SCA service interface. The implementation class itself does not need all the JAX-WS or JAXB annotations. The runtime environment loads the appropriate annotations from the generated classes that the implementation refers to.

5. Create a component using the component implementation. You create a component definition in a composite that references the original WSDL portType interface and the SCA implementation. In SCA, a component is a configured instance of a component implementation. There are other aspects of defining a component that are not shown here such as configuring bindings, configuring property values, defining intents, attaching policy sets, and resolving references. Shown here are the aspects of component creation that are common for all component definitions using the implementation developed in this example. This example also includes bindings that you can modify or omit for other components using this component implementation.

```
<?xml version="1.0" encoding="UTF-8"?>

<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
     targetNamespace="http://account.customer"
         name="accountComposite">
     <component name="BankingComponent">
         <implementation.java class="com.myaccount.account.AccountServiceImpl"/>

         <!-- The @name value matches the contents of the @Service which in turn
              comes from the WSDL portType. -->

         <service name="AccountService">

              <!-- This statement specifies the QName of the WSDL portType,
                    "http://www.myaccount.com/account#AccountService" in the syntax as
                    illustrated in the interface.wsdl statement. -->

             <interface.wsdl interface="http://www.myaccount.com/account#wsdl.interface(AccountService)" />
             <binding.ws/>

  <!-- This example uses the SCA web services binding.  However, it does not matter which SCA binding
       you choose.  -->

          </service>
     </component>
</composite>
```

6. After your component is defined as part of a deployable composite, either directly or recursively through use of one or more layers of components with composite implementation, you are ready to deploy the SCA service by creating an SCA business level application.

# Developing SCA services with existing Java code

You can develop an Service Component Architecture (SCA) service implementation when starting with an existing Java application.

## About this task

There are two ways to develop an SCA service implementation:

- Top-down development starting with an existing Web Services Description Language (WSDL)
- Bottom-up development starting from existing Java code that uses Java Architecture for XML Binding (JAXB) data types

The bottom-up development approach provides a simplified way to begin developing SCA services for the Java developer that does not desire to work with WSDL or XML schema (XSD) authoring or when building new SCA services that expose existing legacy implementations with Java interfaces.

The top-down development approach takes advantage of the interoperable XML-based WSDL, and XSD interface and data definitions.

This task describes the steps when using the bottom-up development approach to develop an SCA service implementation when starting with Java.

When using the bottom-up development methodology, begin by writing a Java interface and implementation that describes the desired business logic. This implementation is then packaged into an application archive file such as a web application archive (WAR) file or a Java archive (JAR) file that is subsequently is used by an SCA component that is configured with deployment information containing the bindings when the SCA application is deployed.

**Note:** It is a best practice to use the top-down methodology to develop SCA service implementations because this approach leverages the capabilities of the XML interface description and provides a greater ease in interoperability across platforms, bindings, and programming languages. To learn more about using the top-down methodology, read about developing SCA services from existing WSDL files.

**Note:** The product uses XML marshalling as defined by JAXB to marshal and unmarshal data across a remotable interface. If you start with a remotable Java interface for your implementation rather than starting with a WSDL portType interface, be careful when selecting the input and output Java data types and ensure you understand which data is preserved across JAXB marshalling and unmarshalling. However, when authoring an implementation on a local interface, you can use any Java type because local interfaces use pass-by-reference semantics, which implies no data is copied.

**Note:** The data marshalling and unmarshalling that is used to instantiate the copying of data over remotable interfaces is defined by the JAXB specification rather than by Java serialization or the java.io.Serializable or java.io.Externalizable interfaces. Because of this behavior, certain existing Java types are not suitable for use on remotable interfaces, as these types are not serialized using Java serialization. For data types that are not annotated, the class is introspected and its Java properties determine the data that is preserved in the copy. For data types that take advantage of JAXB annotations, you can customize the mapping of Java classes to XSD types and of Java instances to XML documents. Custom Java serialization routines such as the readObject() or writeObject() are not applicable in this scenario. The SCA runtime environment takes an XML centric view of the business data and leverages the JAXB standards to define the mappings between the Java programming model and the XML data format on the wire.

## Procedure

1. Access the existing Java interface that you want to expose as an SCA service.
2. Determine if you are using a local or a remotable interface.
   - If you are using a remotable interface, add the @Remotable annotation to the Java interface. The input and output Java data types on the remotable interface use pass-by-value semantics which implies your data is copied using XML serialization as defined by JAXB.
3. Complete the implementation of your SCA service. Write a Java implementation of the generated Java interface that reflects your business logic. The Java implementation is a Plain Old Java Object (POJO) implementation of the original interface.
4. Annotate the Java implementation. Add the @Service annotation to the Java implementation to specify this is an SCA service. When you complete this step, you have created an SCA component implementation.
5. Define a component within a composite definition using this component implementation. In the deinition of your composite, define a component that refers back to the original Java interface and the SCA implementation.
   a. Under the `<component>` element, create a `<implementation.java>` child element that refers to the class name of your POJO component implementation.
   b. Under the `<component>` element, create a `<service>` child element.
   c. Under the `<service>` element, create a `<interface.java ..>` element that refers back to the original Java interface. The @name attribute of the `<service>` element must match the unqualified class name of your Java interface.

   You now have a component with a well-defined component name and service name with a well-defined interface.

   In addition to these aspects of your component definition described by these development procedures, there are other aspects of defining a component. These aspects include adding bindings, configuring property values, defining intents, attaching policy sets, and resolving references. You can create multiple components using this same implementation, but all component definitions are the same with respect to the `<implementation.java>`, `<imterface.java>` and `<service>` elements described in this step.
6. Deploy the SCA service by creating the SCA business level application from a deployable composite.

   In the previous step, you defined a component providing your SCA service within a composite definition. This composite is either a deployable composite, or one that is used recursively as a

composite implementation of a component in a higher-level composite. To learn how to deploy the SCA service, read about deploying and administering business-level applications.

## Results

You have developed an SCA service using the bottom-up methodology by starting with an existing Java interface or implementation.

## Example

The following example illustrates how to create a component implementation of a remotable SCA service interface starting from existing Java code:

1. Start with Java interface `myintf.NameGetter` using type `mypkg.Person`.

```
//NameGetter.java
package myintf;
import mypkg.Person;
public interface NameGetter {
    public String getName(Person p);
}

//Person.java

package mypkg;

public class Person {

    protected String firstName;
    protected String lastName;

    public String getFirstName() {
        return firstName;
    }

    public void setFirstName(String value) {
        this.firstName = value;
    }

    public String getLastName() {
        return lastName;
    }

    public void setLastName(String value) {
        this.lastName = value;
    }
}
```

   In this example, the mypkg.Person class is well-suited for use over a remotable interface, because it follows the JavaBeans pattern and contains a public getter and setter pair for its important data fields. The XML wire format used by the runtime environment will serialize and deserialize this class. However, other existing Java types that do not adhere to the JavaBeans pattern can cause problems as they dol not serialize correctly and data loss occurs. For this reason, it is a best practice to use a top-down development approach, starting from schema definitions and generating JAXB classes for use in the application programming model. See the developing SCA services from existing WSDL files to learn more about the top-down development approach.

2. Because we are creating a service with a remotable interface, add the @Remotable annotation.

```
//NameGetter.java
package myintf;

import mypkg.Person;
import org.osoa.sca.annotations.Remotable;
```

```
@Remotable
public interface NameGetter {
    public String getName(Person p);
}
```

3. Unless you have an existing Java implementation, write a Java implementation of the generated Java interface that reflects your business logic.

```
package myintf;
import mypkg.Person;

public class NameGetterImpl implements NameGetter {

    public String getName(Person p) {
        // Example "business logic"
        return p.getFirstName() + " " + p.getLastName();
    }

}
```

4. Add the @Service annotation to the Java implementation.

```
package myintf;
import mypkg.Person;
import org.osoa.sca.annotations.Service;

@Service(NameGetter.class)
public class NameGetterImpl implements NameGetter {

    public String getName(Person p) {
        // Example "business logic"
        return p.getFirstName() + " " + p.getLastName();
    }

}
```

5. Create a component using the component implementation. You will create a component definition in a composite that references the original Java implementation class, as well as its Java interface. In SCA, a component is a configured instance of a component implementation. There are other aspects of defining a component that are not shown here such as configuring bindings, configuring property values, defining intents, attaching policy sets, and resolving references. Shown here are the aspects of component creation that are common for all component definitions using the implementation developed in this example. This example also includes bindings that you can modify or omit for other components using this component implementation.

```
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
    targetNamespace="http://org.services.naming"
        name="NameServices">

      <component name="NamingServicesComponent">
         <implementation.java class="myintf.NameGetterImpl"/>
         <service name="NameGetter">

             <!-- The interface.java is not required because the run time can introspect it. -->

             <interface.java interface="myintf.NameGetter"/>

             <!-- The choice of bindings is not important for the example.  Here, both the SCA default and
                  web services bindings are configured. -->
             <binding.ws/>
             <binding.sca/>
         </service>
     </component>

</composite>
```

6. After your component is defined as part of a deployable composite, either directly or recursively through use of one or more layers of components with composite implementation, you are ready to deploy the SCA service by creating an SCA business level application.

# Developing SCA service clients

You can develop a Service Component Architecture (SCA) service client starting with either a Java interface or a WSDL file for the SCA service that you want to invoke.

## About this task

You can develop SCA service clients that can both access and invoke an SCA service that are based on the Service Component Architecture specification. An SCA client can consume a diverse set of services such as enterprise beans, web services, and other SCA services, through the capabilities of the respective SCA bindings and by using the Plain Old Java Object (POJO) client programming model.

To develop SCA service clients, you can start with either an existing Web Services Description Language (WSDL) file and use the wsimport tool to generate the Java interface or you can start with an existing Java interface.

**Developing SCA client components starting with an existing WSDL file**

When you have an existing WSDL file that describes your SCA service interface as a WSDL portType, along with XSD schema definitions of your business data, you can use the wsimport tool to generate the SCA Java representations of your business service interfaces and your business data. The wsimport tool generates Java classes that you can use to write a Java implementation that reflects your business logic. You can use the generated output of the proxy class and the JAXB data binding types in your Java client to invoke the SCA service using the simple POJO programming model.

The generated annotated Java classes that correspond to your business data contain all the necessary information that the Java Architecture for XML Binding (JAXB) runtime environment requires to build and parse the XML for marshaling and unmarshaling. In other words, the data programming model is limited to object instantiation and the use of getter and setter methods, and you do not need to write code to convert the data between the XML wire format and the Java application.

Now that you have the generated annotated Java classes, you must use the Java interface and data type classes to create the reference proxy as described in the developing SCA clients starting with a Java interface section.

**Developing SCA client components starting with a Java interface**

When you have a Java interface to your SCA service, obtained either by starting from a WSDL and generating the Java classes or by starting with Java code, use the Java interface and data type classes to create the reference proxy. If your client is designed so that its reference proxy is injected from the SCA container, the Java interface is the same type as your proxy field and this file contains the corresponding @Reference annotation. You can only create the static reference from another SCA component implementation that acts as a client of the original service. If your reference proxy is created programmatically, you must create a proxy variable that has the same type as your Java interface, and use an API such as `CompositeContext.getService(Class <B>interfaze, ...)` to create the reference proxy. The generated Java interface type is the interface parameter that is passed to this API. Read about locating and invoking SCA services to learn more about creating the reference proxy dynamically.

Regardless of whether the proxy is created by injection methods or programmatically, the Java interface is the class of the proxy and the generated JAXB types are the parameter types which includes inputs, outputs, and exceptions.

**Considerations for local and remotable interfaces**

It is important to understand that a remotable interface uses an XML wire format for data. Therefore, clients must use a JAXB-based programming model for the data types. In contrast, a local interface uses pass-by-reference semantics, so there is no data copy. Using the local interface, data is read and written without any special programming model such as JAXB.

Though WSDL-based interfaces are always remotable, you can also mark a Java interface that is not generated from a WSDL file as remotable by annotating it with the @Remotable annotation. The @Remotable annotation results in a data copy with XML serialization as defined by JAXB.

Defining the remotable interface is straightforward when you start with a WSDL interface, because you use the wsimport tool to generate the JAXB data types that you use when you write your SCA client. The remotable interface is less apparent when starting from a remotable Java interface, unless the Java types are decorated with JAXB annotations. XML serialization behaves differently than Java serialization. For an POJO that is not annotated, Java serialization preserves instance data including private fields, whereas JAXB serialization preserves JavaBeans properties.

The focus of this topic is the use of remotable interfaces.

You can develop a component that consumes or acts as a client of the target service using a component reference. In addition to consuming a service from another component's reference, the product also provides a mechanism for consuming an SCA service over the default binding from a non-SCA component.

## Procedure

1. Determine if you are developing the SCA service client starting with an existing WSDL file or with an existing Java interface.
2. Develop the client Java interfaces and data types from a WSDL file if you are not starting with an existing Java interface. Use the wsimport command to generate the SCA service client Java interfaces.
3. Create the reference proxy based on the Java interface.
   a. Create a reference proxy field or setter method that has the same type as the generated Java interface
   b. Annotate this field or setter with the @Reference annotation.

   Now you have completed the steps required to add the reference to your Java component implementation
4. Create a component definition using the Java implementation.

   In the composite definition, add a `<reference>` element that refers back to the original interface and the field or setter of your SCA implementation. The reference is added as a child element of your component. The component is part of a composite definition.

   The `<reference>` name attribute must correspond to the field or setter that contains the @Reference annotation. For a field that contains the @Reference annotation, the name attribute must match exactly. For a setter that contains the @Reference annotation, use the usual Java conventions for translating an annotated setter into a corresponding field, which in turn must match the name attribute.

   For the interface:

   - If your SCA client development started with an existing WSDL file, create an `<interface.wsdl>` element as a child element of the `<reference>` element that points to the WSDL portType.
   - If your SCA client development started from existing Java interface, create an `<interface.java>` element as a child element of the `<reference>` element that points to the original Java interface. This is optional, since the runtime environment can introspect the Java interface.

   In addition to these aspects of your component definition described by these development procedures, there are other aspects of defining a component. These aspects include adding bindings, configuring property values, defining intents, attaching policy sets, and resolving references. You can create multiple components using this same implementation, but all component definitions are the same with respect to the `<implementation.wsdl>` element and `<reference>` element described in this step.
5. Deploy the SCA component by creating the SCA business level application from a deployable composite.

   In the previous step, you defined a component providing your SCA service within a composite definition. This composite is either a deployable composite, or one that is used recursively as a

composite implementation of a component in a higher-level composite. To learn how to deploy the SCA service, read about deploying and administering business-level applications.

## Results

You have created an SCA component that can consume an existing SCA service using a WSDL or Java interface.

## Example

The following example illustrates using an existing WSDL interface to generate a Java interface that is used to create a Java implementation that is an SCA client. If you are starting with an existing Java interface, begin with step 4 to follow this example.

1. Copy the following sample `account.wsdl` WSDL file to a temporary directory.

```
<?xml version="1.0" encoding="UTF-8"?>

<wsdl:definitions xmlns:soap="http://schemas.xmlsoap.org/wsdl/soap/"
     xmlns:wsdl="http://schemas.xmlsoap.org/wsdl/"
     xmlns:account="http://www.myaccount.com/account"
     targetNamespace="http://www.myaccount.com/account"
     name="AccountService">

      <wsdl:types>
         <schema targetNamespace="http://www.myaccount.com/account"
             xmlns="http://www.w3.org/2001/XMLSchema"
             xmlns:xsd="http://www.w3.org/2001/XMLSchema"
             xmlns:account="http://www.myaccount.com/account">

               <element name="computeAccountAverage">
                 <complexType>
                     <sequence>
                         <element name="account" type="account:Account" />
                         <element name="days" type="xsd:int" />
                     </sequence>
                 </complexType>
             </element>
             <element name="computeAccountAverageResponse">
                 <complexType>
                     <sequence>
                         <element name="return" type="xsd:float" />
                     </sequence>
                 </complexType>
             </element>

             <complexType name="Account">
                 <attribute name="accountNumber" type="xsd:int" />
                 <attribute name="accountID" type="xsd:string" />
                 <attribute name="accountType" type="xsd:string" />
                 <attribute name="balance" type="xsd:float" />
             </complexType>

          </schema>
     </wsdl:types>

     <wsdl:message name="computeAccountAverageRequest">
         <wsdl:part element="account:computeAccountAverage"
             name="parameters" />
     </wsdl:message>

     <wsdl:message name="computeAccountAverageResponse">
         <wsdl:part element="account:computeAccountAverageResponse"
             name="parameters" />
     </wsdl:message>

     <wsdl:portType name="AccountService">
         <wsdl:operation name="computeAccountAverage">
             <wsdl:input message="account:computeAccountAverageRequest" name="accountReq"/>
             <wsdl:output message="account:computeAccountAverageResponse" name="accountResp"/>
         </wsdl:operation>
```

```
        </wsdl:portType>

        <wsdl:binding name="AccountServiceSOAP" type="account:AccountService">
            <soap:binding style="document"
                transport="http://schemas.xmlsoap.org/soap/http" />
            <wsdl:operation name="computeAccountAverage">
               <soap:operation
                    soapAction="computeAccountAverage" />
                <wsdl:input name="accountReq">
                   <soap:body use="literal" />
                </wsdl:input>
                <wsdl:output name="accountResp">
                    <soap:body use="literal" />
                </wsdl:output>
            </wsdl:operation>

         </wsdl:binding>

        <wsdl:service name="AccountWSDLService">
            <wsdl:port binding="account:AccountServiceSOAP"
                name="AccountServicePort">
                <soap:address location=""/>
            </wsdl:port>
        </wsdl:service>
    </wsdl:definitions>
```

2. Run the wsimport command from the *app_server_root*/bin/ directory.

   Windows

   ```
   app_server_root\bin\wsimport.bat -keep -verbose account.wsdl
   ```

   Linux AIX HP-UX Solaris Run the wsimport command,

   ```
   app_server_root/bin/wsimport.sh -keep -verbose account.wsdl
   ```

   After generating the template files using the wsimport command, the following Java files are generated:

   ```
   com/myaccount/account/Account.java
   com/myaccount/account/AccountService.java
   com/myaccount/account/AccountWSDLService.java
   com/myaccount/account/ComputeAccountAverage.java
   com/myaccount/account/ComputeAccountAverageResponse.java
   com/myaccount/account/ObjectFactory.java
   com/myaccount/account/package-info.java
   ```

3. Identify the generated Java interface from the generated classes.

```
//
// Generated By:JAX-WS RI IBM 2.1.1 in JDK 6 (JAXB RI IBM JAXB 2.1.3 in JDK 1.6)
//
package com.myaccount.account;
...
@WebService(name = "AccountService", targetNamespace = "http://www.myaccount.com/account")
...
public interface AccountService {
    /**
     *
     * @param days
     * @param account
     * @return
     *     returns float
     */
    @WebMethod(action = "computeAccountAverage")
    @WebResult(targetNamespace = "")
    @RequestWrapper(localName = "computeAccountAverage", targetNamespace = "http://www.myaccount.com/account",
         className = "com.myaccount.account.ComputeAccountAverage")
    @ResponseWrapper(localName = "computeAccountAverageResponse", targetNamespace = "http://www.myaccount.com/account",
         className = "com.myaccount.account.ComputeAccountAverageResponse")
    public float computeAccountAverage(
        @WebParam(name = "account", targetNamespace = "")
        Account account,
        @WebParam(name = "days", targetNamespace = "")
        int days);

}
```

This code example is a Java interface, not merely a Java class. The @WebService annotation is present in this Java interface. It is important to know that this example is not the same as the generated @WebServiceClient class, com.myaccount.account.AccountWSDLService. This class is not an interface and is actually not needed in your SCA application.

4. Now that you have Java interface either by generating the Java interface from a WSDL file or you have an existing Java interface, you are ready to develop your SCA client from the Java interface.
5. Place the @Reference annotation on a public or protected field or setter, with the same type as your Java interface.

```
package com.myaccount.client;

import bank.process.BankProcess;
import org.osoa.sca.annotations.Reference;
import org.osoa.sca.annotations.Service;

import com.myaccount.account.*;

@Service(BankProcess.class)
public class AccountClientComponent implements BankProcess {

   // Note the type, 'AccountService', is the Java interface generated from
   // from the WSDL portType
    private AccountService accountServiceRef;

    //
    // Injected by the SCA container
    //
    @Reference
    public void setAccountServiceRef(AccountService accountServiceRef) {
        this.accountServiceRef = accountServiceRef;
    }

    public String someMethod(String input) {

        //... some business logic ...

        //  We'll show a simple example of JAXB API usage
        ObjectFactory factory = new ObjectFactory();
        Account account = factory.createAccount();
        account.setAccountNumber(4);
        account.setAccountID("CHECKING");

        int days = 5;

        float avg = accountServiceRef.computeAccountAverage(account, days);

        //... the rest of the business logic ...
    }
}
```

6. Create a component using the component implementation. When using a WSDL portType interface, you must create component definitions in the composite definition that references the original portType along with the SCA Java implementation. In SCA, a component is a configured instance of a component implementation. There are other aspects of defining a component that are not shown here such as configuring bindings, configuring property values, defining intents, attaching policy sets, and resolving references. Shown here are the aspects of component creation that are common for all component definitions using the implementation developed in this example. This example also includes bindings that you can modify or omit for other components using this component implementation.

```
<?xml version="1.0" encoding="UTF-8"?>

<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
     targetNamespace="http://bank.process/customer"
         name="bpComposite">

      <component name="BankProcessComponent">

          <implementation.java class="com.myaccount.client.AccountClientComponent"/>
         <!-- The @name attribute corresponds to the setter that is annotated with the @Reference annotation. -->

         <reference name="accountServiceRef">
```

```
             <!-- This statement specifies the QName of the WSDL portType,
                   "http://www.myaccount.com/account#AccountService" in the syntax as
                  illustrated in the interface.wsdl statement.  -->

            <interface.wsdl interface="http://www.myaccount.com/account#wsdl.interface(AccountService)" />
            <binding.ws uri="http://localhost:9080/BankingComponent/AccountService"/>

  <!-- This example uses the SCA web services binding.  However, it does not matter which specific binding
 you choose.  You can also choose to use the SCA default binding or the SCA EJB binding.  -->

         </reference>
     </component>
</composite>
```

7. Configure the composite definition when starting with a Java interface.

   The following snippet is another example of the syntax if you develop an SCA client starting with a Java interface rather than with a WSDL portType. To simplify this example, use the same AccountService Java interface from the previous step but in this case, assume that it was not generated from a WSDL file.

```
<?xml version="1.0" encoding="UTF-8"?>

<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
     targetNamespace="http://bank.process/customer"
         name="bpComposite">

      <component name="BankProcessComponent">

         <implementation.java class="com.myaccount.client.AccountClientComponent"/>

         <!-- The @name value corresponds to the setter that is annotated with the @Reference annotation. -->
                <reference name="accountServiceRef">

              <!-- Because the runtime can introspect the interface, it is unnecessary to specify
                   the interface.java in the composite definition. This is what the interface looks like if you include it.

                          <interface.java interface="com.myaccount.account.AccountService"/>  -->

               <!-- The SCA binding type is omitted. It does not matter which specific SCA binding you choose. -->
         </reference>
     </component>
</composite>
```

8. After a component is defined as part of a deployable composite, either directly or recursively through use of one or more layers of components with composite implementation, you are now ready to deploy the SCA component by creating a SCA business level application.

# Using business exceptions with SCA interfaces

You can implement exceptions for remotable interfaces in the Service Component Architecture (SCA) environment to provide additional flow of control for error conditions to meet the needs of your business application.

## About this task

To develop SCA service implementations, you can use either a top-down development approach starting with an existing Web Services Description Language (WSDL) file or you can use a bottom-up development approach starting from an existing Java interface or implementation. When using either the top-down or bottom-up development methodologies, you can use tools to map business exceptions on remotable interfaces.

In order to achieve the SOA goal of providing an interoperable platform that is both language and technology neutral, the SCA runtime environment takes an XML-centric view of interfaces and data. When working with Java code, the Java API for XML-Based Web Services (JAX-WS) standard is used to define the mapping between Java code and the XML-based Web Services Description Language (WSDL) file. This mapping also includes the Java programming model with respect to exceptions. Exceptions for remotable interfaces in the SCA environment is defined by the JAX-WS specification. This topic describes the best practices for using business exceptions with SCA interfaces.

### Differences between business exceptions and fault beans

To better understand the implications of implementing business exceptions in an SCA environment, it is helpful to understand differences between an exception and a fault bean.

The JAX-WS specification distinguishes between a checked exception and the fault bean that it wrappers. However, this distinction might not be clear because a single class can serve the checked exception and the fault bean functions, especially when you use the bottom-up approach of developing an SCA service starting with a Java interface. When you use the top-down development approach of developing an SCA service starting with a WSDL file, section 2.5 of the JAX-WS specification describes the wrapper pattern for how the fault message maps to a Java checked exception that wraps a fault bean. The fault bean maps to the fault element and in SCA environments, the mapping is defined by Java Architecture for XML Binding (JAXB) data binding. The fault bean represents the cross-platform view of the fault message data and includes a schema description. You can use the Java exception within the Java runtime environment and as part of the Java programming model. However, the exception is not part of the interoperable data representation.

When developing SCA services using the bottom-up approach, the distinction between an exception, the fault bean, and the mapping from Java to WSDL or XSD schema is clear if you follow the wrapper pattern described in section 2.5 of the JAX-WS specification. If you have existing Java exceptions, use the standard mapping defined in section 3.7 of the JAX-WS specification for service specific exceptions. In SCA environments, these service specific exceptions are referred to as business exceptions. The mapping for the business exceptions is different than the mapping described in section 2.5 of the JAX-WS specification. Because this wrapper pattern only applies for certain exceptions, this approach has limitations when using the bottom-up development approach. The possible limitations of using the wrapper pattern to implement error handling when using bottom-up development of SCA applications provides additional reasons to consider the advantages of the best practice of top-down development of SCA applications.

### Top-down development, starting from a WSDL operation with fault messages

It is a best practice to use the top-down methodology to develop SCA service implementations because this approach leverages the capabilities of the XML interface description and provides a greater ease in interoperability across platforms, bindings, and programming languages. A WSDL operation can be defined, along with one or more fault messages, provided each fault message is defined in terms of a fault element. When the wsimport command-line tool is used to generate Java code the tool generates Java exception code that wraps a fault element in the format specified by the Java API for XML-Based Web Services (JAX-WS) specification, section 2.5.

### Bottom-up development, starting from a Java operation with throws clause

Bottom-up development of SCA services occurs when you start with existing Java code. Using this development approach, do not design a remotable interface that might cause a technology exception such as java.sql.SQLException. This exception is more appropriate for a local interface rather than a coarse-grained remotable interface.

## Procedure

1. For top-down development of SCA applications, implement a wrapper pattern for business exceptions.
   The wrapper pattern is based on section 2.5 of the JAX-WS specification.
   a. Obtain your WSDL file; for example:

```
<wsdl:types>
    ...
    <element name="errorCode" type="xsd:int"/>
    ...
</wsdl:types>

<wsdl:message name="BadInputMsg">
    <wsdl:part element="tns:errorCode" name="parameters"/>
</wsdl:message>
```

```
<wsdl:portType name="GuessAndGreet">
    <wsdl:operation name="sendGuessAndName">
            <wsdl:input.../>
            <wsdl:fault message="tns:BadInputMsg" name="BadInputMsg"/>
```

b. Generate the Java artifacts using the wsimport tool. You can define the fault according to section 2.5 of the JAX-WS specification; for example:

```
Interface
   public Person sendGuessAndName(...) throws BadInputMsg;
```

c. Wrap an exception in a fault; for example:

```
import javax.xml.ws.WebFault;

@WebFault(name = "errorCode", targetNamespace = "....")
public class BadInputMsg extends Exception
{
    private int faultInfo;

    public BadInputMsg(String message, int faultInfo) {
        super(message);
        this.faultInfo = faultInfo;
    }

    public BadInputMsg(String message, int faultInfo, Throwable cause) {
        super(message, cause);
        this.faultInfo = faultInfo;
    }

    public int getFaultInfo() {
        return faultInfo;
    }
}
```

2. For bottom-up development of SCA applications, implement or convert the exception to follow the wrapper pattern or use the default mapping for of a JAX-WS service specific exception.

   If you have a Java business exception, the complexity of this scenario increases, especially if your exception wraps fault data. For example, the exception wraps data such as an error code or an object that it needs to provide to the client that receives the exception. In this scenario, there are two options:

   - Convert the Java business exception to follow the wrapper pattern as described in section 2.5 of the JAX-WS specification.

     Using the wrapper pattern for the exception enables the exception to map easily from the WSDL to Java code format and then from the Java code to WSDL format. If you modify the exception to follow the wrapper pattern, you can use the wsgen tool to convert from Java code to WSDL and later use the wsimport tool to convert from WSDL to Java code, the exception is similar to the one that you modified. To achieve this end goal, you must perform the following steps:

     a. Add constructors that take the fault bean as input parameters.
     b. Implement a public getFaultInfo() method that returns the fault bean.
     c. Add the @javax.xml.ws.WebFault annotation. See the example that wraps an exception in a fault.

   - Use the default mapping of a JAX-WS service specific exception or business exception as described in section 3.7 of the JAX-WS specification.

     If you use the wsgen command-line tool to generate the WSDL, the tool uses this pattern for business exceptions. If you do not generate the WSDL file before deployment, the application server runtime environment implicitly generates the business exception using this pattern.

     Use this option when you:

     – cannot change the exception class to follow the JAX-WS wrapper pattern.
     – rely on the runtime environment to map the Java code into WSDL such as declaring a `<binding.ws>` binding on a service that is deployed without a WSDL file.

     Either of these options work without any additional complexity as long as the exception does not contain fault data.

For exceptions with fault data, the data is handled correctly for each field that contains a public getter or setter method. However, data is lost without a getter or setter pair. In other words, serialize or deserialize the exception by viewing it as a Java code.

When using this second option, the following items are important:

- The supported fault pattern is not easily determined. One exception with fault data and also with the getter and setter methods is that some are handled correctly while others are not. Running the wsgen tool at development time generates the schema based on the exception getter methods without assuring that the corresponding setter methods exist in order to populate the exception during unmarshalling.
- If you run wsimport tool against the generated WSDL, you get a different exception class. Your client and service programming model are different which might confuse the Java programmer. However, this generated Java exception follows the pattern described in the JAX-WS specification in section 2.5. You might need to add customization for JAXB data binding in order to generate the client. The results can produce exception names similar to `MyException_Exception`.
- Although the service-specific exception pattern is described in section 3.7 of the JAX-WS specification, not all details for the pattern are specified. Other software implementing JAX-WS might implement the pattern differently. This is not critical, since the WSDL file is interoperable across platforms.

## Example

The following examples illustrates using the bottom-up development of SCA applications and using the business exception mapping as described in section 3.7 of the JAX-WS specification.

### Example 1: No fault

The string message is the fault in this example, and it is serialized and deserialized successfully.

```
public class RealSimpleException extends Exception {
    public RealSimpleException(String message) {
        super(message);
    }
    public RealSimpleException(String message, Throwable cause) {
        super(message, cause);
    }
}
```

### Example 2: Exception as JavaBeans

This example works correctly because the string `userdata` fault has associated public getter and setter methods. The string message is also handled correctly.

```
public class TestException extends Exception {

    private String userdata;

    public TestException(String message) {
        super(message);
    }

    public TestException(String message, String userdata) {
        super(message);
        this.userdata = userdata;
    }

    public String getUserdata() {
        return userdata;
    }

    public void setUserdata(String userdata) {
```

```
        this.userdata = userdata;
    }

}
```

### Example 3: Exception does not follow pattern

This example does not work correctly because the errorCode fault data does not have a setter method. The SCA runtime is not able to correctly determine how to populate the exception with this fault data. The exception occurs, but it is displayed with data loss.

```
package java.sql;

public class SQLException extends Exception ... {
 ...
 public SQLException(String theReason, String theSQLState, int theErrorCode) ...

 public int getErrorCode()
}
```

## What to do next

### Increase portability of your exception classes in top-down development

One issue that you might encounter with Java exceptions generated from WSDL in the top-down manner is that the fault bean might not be Java-serializable. In other words, the fault bean might not implement java.io.Serializable. This does not present a problem if the bindings that your application uses are in XML wireformat because, in that scenario, XML serialization is used instead of Java serialization. However, XML serialization limits the usefulness of your exception class. Therefore, it might not be suitable to use with SCA binding configurations using a wireformat with Java serialization, or in other contexts in which Java serialization is used to serialize and deserialize an exception.

To avoid this limitation, annotate your schema definition for the fault element type with a JAXB customization designed for this purpose. When this customization is present, the JAXB type that is generated, that corresponds to the fault bean, is marked as implementing the java.io.Serializable interface, and is therefore Java serializable, in addition to being serializable to XML, because the class is also still a conforming JAXB type.

### Example:

```
<schema targetNamespace="http://com.mycompany/banking/" jaxb:version="2.0"
  xmlns:jaxb="http://java.sun.com/xml/ns/jaxb"
  xmlns="http://www.w3.org/2001/XMLSchema">
   <annotation>
     <appinfo>
       <jaxb:globalBindings>
         <jaxb:serializable uid="1"/>
      </jaxb:globalBindings>
     </appinfo>
   </annotation>

    <!-- Continue with the rest of the schema definition-->

 </schema>
```

### SCA programming tip for binding neutrality

The JAX-WS defined mapping between exceptions in Java and an XML wireformat relies on the use of the fault bean to pass back data from the service provider throwing the exception to the client that is catching it. Normal Java-centric mechanisms, such as exception chaining, are not preserved in mapping between the Java application and the wire. Therefore, the best way to write application code that can be used across binding configurations using either of a Java serialization wireformat or an XML wireformat is to rely exclusively on the fault bean for communicating useful application level data relating to the exception.

Even though using a chained exception across a binding that uses a Java-serialization based wireformat works fine, using a chained exception across a binding using XML wireformat might not work. Therefore relying on a chained exception would not be a recommended practice in an SCA environment, because SCA strives to provide a binding-neutral programming model.

# Considerations for developing SCA applications using EJB bindings

When developing Service Component Architecture (SCA) applications that you intend to use with Enterprise JavaBeans (EJB) bindings, keep in mind that the SCA EJB binding is architected in a Java-centric manner, in contrast to the XML-centric implementations of the SCA default binding and the SCA web services binding.

The EJB transports marshal and unmarshal application data into the wire format by using Java serialization, whereas the web services and default bindings use XML serialization. This difference also affects the programming model in that the SCA clients and implementations using the EJB binding must use java.io.Serializable types, in contrast to the Java Architecture for XML Binding (JAXB) data types-based programming model that is used for the SCA default and web services bindings.

## SCA reference

In this case, you have an existing EJB that you want to invoke with an SCA client using a reference that is configured with an EJB binding.

When you develop an SCA client that will invoke an existing EJB using the SCA EJB binding, you must use a Java interface when developing the SCA client rather than using a WSDL interface. The EJB binding marshalling of application data into the wire data format is performed using Java serialization, not XML serialization as defined by JAXB.

To learn more about SCA references, read about developing SCA service clients. However, when you are using the SCA EJB binding, the information in this topic takes precedence.

Because you obtain the Java interface and parameter types from the EJB provider for use in your client, you do not have to worry about the effects of marshalling and unmarshalling when writing your client. However, when you provide these data types across new services, problems can occur if you pass these data types across new services, because they might not serialize correctly over other bindings, such as the default binding, because of the difference in Java serialization and the JAXB XML marshalling and unmarshalling.

The following example illustrates the problematic scenario of starting with an existing EJB interface and using a Java serializable data type that does not serialize well using JAXB marshalling and unmarshalling.

```
public interface NameService extends javax.ejb.EJBObject {

    public String computeName(Person p) throws RemoteException;
}

// This snippet is intended as an example of a type that is problematic.
public class Person implements java.io.Serializable {

    private int code;
    private String name;

    // The code field must be passed into constructor.  However, this causes problems for
    // for SCA default and web services bindings that use JAXB marshalling/unmarshalling.

    public Person(int code) {
        this.code = code;
    }

    public Person() {
    }

    public String getName() {
        return name;
```

```
    }

    public void setName(String value) {
        this.name = value;
    }

}
```

The following SCA client A example works correctly. The Person object that is instantiated directly in the ClientAImpl implementation is correctly marshalled to invoke the EJB with a remote interface of NameService.

```
// Client A  ClientAImpl.java
 .....
@Reference
public NameService nameService

public someClientMethod() {
    // No problem when Person object is instantiated by client
    Person person = new Person(5);
    String name = nameService.computeName(person);
}
```

In contrast, the following example demonstrates the problem with the Person type. The client code has been refactored so that it contains a reference to NameService, and it obtains the Person object that is passed into the computeName method over a new remotable interface, rather than constructing it directly.

```
// Problem client interface

import org.osoa.sca.annotations.Remotable;
@Remotable
public interface PersonFilter {
     boolean filterPerson(Person p);
}

// Problem client implementation

@Service(PersonFilter.class)
public class PersonFilterImpl implements PersonFilter {
     @Reference
     public NameService nameService

     boolean filterPerson(Person p) {
     // ...  business logic
    String name = nameService.computeName(person);
     // ...  business logic
     }
}
```

If the PersonFilterImpl class receives a Person object from the client over the PersonFilter interface and the implementation is invoked using the SCA default binding, the data is not handled correctly. The default binding does not preserve the code field of the Person object that is passed to the PersonFilterImpl class.

For a class without JAXB annotations, JAXB marshalling and unmarshalling preserves JavaBeans properties, but not private data such as the code field, which does not have a setter and is only established in the constructor. When the Person object is passed to the NameService EJB, the code value is set to the default value of 0 regardless of what the PersonFilter client passed to the PersonFilterImpl class.

If the Person type was written in the JavaBeans style with getters and setters for all important data, then this type works correctly in the example for the PersonFilterImpl client. However, if you are consuming an existing EJB, you do not have control over the types it already uses on its interface. Not all existing Java types are optimal for SCA Java programming. To address the problems in this example, you must create a

new type for use on the PersonFilter interface and translate the data for this type into a Person object within the PersonFilterImpl class which directly invokes the EJB with the remote interface NameService.

In this example, if the PersonFilter interface was defined as a local interface, then the concerns with preserving data integrity do not apply. The runtime environment performs pass-by-reference semantics across local interfaces that are appropriate for tightly-coupled clients and services such that no data is copied.

### SCA service

If you write a new SCA service and intend to expose it over the SCA EJB binding so that an EJB client can invoke the service, it is a best practice to develop the SCA service using the top-down methodology starting with an existing WSDL file or XSD schema and generating the JAXB classes that are used to write the service implementation. Using this approach, you can easily address the differences between Java serialization and JAXB marshalling and unmarshalling by specifying that the generated JAXB classes are Java serializable.

To enable the generated JAXB classes to work correctly over the SCA EJB binding, add the serializable customization to the schema definition so that the generated JAXB classes are Java serializable and implement the java.io.Serializable interface. For example:

```
<schema targetNamespace="http://com.mycompany/banking/" jaxb:version="2.0"
 xmlns:jaxb="http://java.sun.com/xml/ns/jaxb"
 xmlns="http://www.w3.org/2001/XMLSchema">
  <annotation>
    <appinfo>
      <jaxb:globalBindings>
        <jaxb:serializable uid="....."/>
     </jaxb:globalBindings>
    </appinfo>
  </annotation>

   <!-- Continue with the rest of the schema definition-->

</schema>
```

As a result, you can use your Java implementation with the generated JAXB data types over the EJB binding, which uses Java serialization. At this point, because you have the generated JAXB artifacts, you can also use your Java implementation with the generated JAXB data types over the SCA default and SCA web services bindings, which use XML serialization as defined by JAXB.

If you develop your SCA service using the bottom-up approach starting with Java code, you must use types that implement the java.io.Serializable interface as required when writing an EJB. See the developing SCA services with existing Java code documentation for more information regarding requirements for your user-defined types. Also, see the SCA reference section to learn how to avoid problems with your user-defined types when using EJB bindings because of the differences between Java serialization and JAXB marshalling and unmarshalling.

## Specifying bindings in an SCA environment

After you develop an Service Component Architecture (SCA) component, you can use bindings to specify how SCA services and references enable the component to communicate with other applications.

### About this task

Services and references enable a component to communicate with other applications. By design, however, the SCA services and references say nothing about how this communication occurs. Bindings are used to determine how a component communicates with the world outside its domain. SCA services use bindings to describe the access mechanism that clients must use to call the service. SCA references use bindings

to describe the access mechanism that is used to call a service. Depending on what the SCA component is communicating with, a component might or might not have explicitly specified bindings.

The product supports the following binding types:

- SCA binding

  The SCA binding is also referred to as the default binding. It is the binding that is used when no other binding is specified for configuration of a component reference or service. It is the natural binding to use when your SCA client invokes an SCA service in the same domain.

  SCA default bindings are not compatible across implementations by architecture; however, some interoperability scenarios are enabled between Open SCA and Classic SCA as implemented in the BPM Suite of products like WebSphere Process Server.

  Components communicating within the same domain only need to explicitly configure a default binding on a service or reference when there is at least one non-default binding, such as the SCA web services binding or the SCA EJB binding, that is also configured.

- Web service binding

  The SCA web services binding applies to the services and references of components. The web service binding is designed for SOAP-based Web Services-Interoperability (WS-I) compliant web services. This binding defines the manner in which a service is made available as a web service, and in which a reference can invoke or access a web service. The web service binding enables SCA applications to expose SCA services as web services to external clients that might or might not be implemented as an SCA component. This binding is a Web Services Description Language (WSDL)-based binding which means that the web service binding either references an existing WSDL binding or enables you to specify enough information to generate a WSDL file. When an existing WSDL binding is not referenced, you can generate a WSDL binding. You can further customize an SCA web services binding using SCA policy sets.

  Web services technology plays an important role in most SOA solutions relevant today, including SCA. The SCA web service binding type enables SCA applications to expose services as web services to external clients as well as enabling SCA components access to external web services. External clients that access SCA services exposed as web services may or may not be implemented as an SCA component. You can use the web service binding element `<binding.ws>` within either a component service or a component reference definition. When the web service binding is used with a component service, this binding type enables clients to access a service offered by a particular component as a web service. When the web service binding is used with a component reference, components in an SCA component can consume an external web service and access as if it was any other SCA component. Only WSDL Version 1.1 is supported.

- EJB binding

  EJB session beans are a common technology used to implement business services. The ability to integrate SCA with services based on session beans is useful because it preserves the investment incurred during the creation of those business services, while enabling the enterprise to embrace the newer SCA technology in incremental steps. The simplest form of integration is to simply enable SCA components to invoke session beans as SCA services. There is also a need to expose services such that they are consumable by programmers skilled in the EJB programming model. This enables existing session bean assets to be enhanced to exploit newly deployed SCA services without the EJB programmers having to learn a new programming model.

  The SCA EJB binding enables SCA to integrate with existing Java EE applications. It exposes SCA services as stateless session beans to external clients. The binding element `<binding.ejb>` is used within a component service or component reference definition. Support is provided for the EJB binding when using both 2.x and 3.0 EJB styles for both the SCA service and reference.

- JMS binding

  Use the SCA Java Message Service (JMS) binding to compose and assemble SCA services from new and existing services that are available using the JMS programming interface. By taking advantage of

the ability to integrate SCA with existing services based on JMS, you can preserve your investment in enterprise messaging technology, while enabling the enterprise to embrace the new SCA technology in incremental steps.

The SCA JMS binding enables an open, implementation neutral, service-oriented description of the SCA service assembly and composition. Use the binding element `<binding.jms>` within a component service or component reference definition. SCA services using the JMS binding are exposed using the Java EE Connector Architecture (JCA)-based messaging provider in WebSphere Application Server.

The product supports the default messaging provider or WebSphere MQ as the messaging engine.

- Atom binding

  Use the Atom binding to work with services that provide or consume entries described in the Atom Syndication Format and Atom Publishing Protocol. An SCA component can reference existing external web feeds defined using the Atom protocol and work with them inside a Java implementation. Also, you can use the Atom binding to compose new services and expose them as an Atom feed.

- HTTP binding

  Use the HTTP binding to expose SCA services for consumption by remote JavaScript-enabled web browser clients. Using this binding, clients can invoke Remote Procedure Calls (RPC) to server-side SCA components.

### Procedure

1. Select a binding type to use for an SCA component.
   - Use the SCA default binding when you want to invoke an SCA service from an SCA client.
   - Use the SCA web services binding to specify that an SCA service is made available as a web service or an SCA reference can invoke a web service.
   - Use the SCA EJB binding to integrate SCA with services based on session beans.
   - Use the SCA JMS binding to compose and assemble SCA services from new and existing services.
   - Use the Atom binding to expose collections of data as an Atom feed or to reference existing external Atom feeds.
   - Use the HTTP binding with a wire format of JSON-RPC to expose services to remote web browser clients.
2. Configure the selected binding and use it in an SCA component or application.

### Results

SCA components can use the configured bindings to communicate with other SCA services and references.

### What to do next

Deploy the SCA component or application.

## Configuring the SCA default binding

You can configure the Service Component Architecture (SCA) default binding for services and references.

### About this task

Bindings determine how a component communicates with the world outside its domain. Services use bindings to describe the access mechanism that clients must use to call the service. References use bindings to describe the access mechanism used to call a service. The SCA binding is also referred to as the default binding. The default binding is the binding that is used when no other binding is specified for a configuration of a component reference or service. Use this binding when an SCA client invokes an SCA service in the same domain. It is not intended to be interoperable in any way with other implementations of SCA runtime environments.

## Procedure

- Configure an SCA service with the SCA default binding.

  If the service is only exposed over the default binding, then you do not need to explicitly add the <binding.sca> element because this binding is default binding for SCA. If your SCA service has more than one binding and the SCA default binding must be one of them, you must specify the <binding.sca> element in the composite definition.
- Configure an SCA reference with the SCA default binding.

  For the reference, you also do not need to specify the <binding.sca> element. For an reference with a default binding, the reference specifies a target attribute indicating the target service. To indicate the target at the reference, specify target=componentName/serviceName. If only one service exists for the service component, then you only need to specify the componentName; for example: target=ComponentName.

## Results

You have implicitly or explicitly configured the SCA default binding for your SCA service or reference.

## Example

The following examples illustrate multiple scenarios for configuring the SCA default bindings.

### Top level composite with SCA service binding

```
<?xml version="1.0" encoding="UTF-8"?>

   <composite xmlns="http://www.osoa.org/xmlns/sca/1.0" targetNamespace="http://mysca/samples" name="MyComposite">

      <component name="HelloWorldServiceComponent">
         <implementation.java class="test.HelloWorldImpl"/>
      </component>

   </composite>
```

### Top level composite with SCA reference binding

```
<?xml version="1.0" encoding="UTF-8"?>

   <composite xmlns="http://www.osoa.org/xmlns/sca/1.0"  targetNamespace="http://mysca/samples"
       name="ClientComposite">

      <component name="ClientComponent">
        <implementation.java class="test.GreetingsServiceImpl"/>
        <reference name="helloWorldService" target="TargetComponent"/>
      </component>

   </composite>
```

**OR:**

```
<?xml version="1.0" encoding="UTF-8"?>

   <composite xmlns="http://www.osoa.org/xmlns/sca/1.0"  targetNamespace="http://mysca/samples"
        name="ClientComposite">

      <component name="ClientComponent">
        <implementation.java class="test.GreetingsServiceImpl"/>
        <reference name="helloWorldService" target="TargetComponent/HelloWorld"/>
        <!-- compName/serviceName -->
        </component>

   </composite>
```

### Top level composite with SCA service binding with transaction policy attribute defined

```
<?xml version="1.0" encoding="UTF-8"?>

   <composite xmlns="http://www.osoa.org/xmlns/sca/1.0"  targetNamespace="http://neworder/sca/jdbc"
       name="NewOrderComposite">

      <component name="NewOrderServiceComponent">
         <service name="NewOrderService" requires="propagatesTransaction.false"/>
         <implementation.java class="neworder.sca.jdbc.NewOrderServiceImpl" requires="managedTransaction.local"/>
      </component>

   </composite>
```

## Top level composite with SCA service binding supporting WSDL interface

```
<?xml version="1.0" encoding="UTF-8"?>

   <composite xmlns="http://www.osoa.org/xmlns/sca/1.0"  targetNamespace="http://mysca/samples"
         name="ClientComposite">

        <component name="ClientComponent">
           <service name="HelloWorldService">
             <interface.wsdl interface="http://helloworld#wsdl.interface(HelloWorld)"/>
           </service>
          <implementation.java class="test.HelloWorldImpl"/>
         </component>

   </composite>
```

## Top level composite with SCA reference binding supporting WSDL interface

```
<?xml version="1.0" encoding="UTF-8"?>

    <composite xmlns="http://www.osoa.org/xmlns/sca/1.0" targetNamespace="http://mysca/samples" name="ClientComposite">

       <component name="ClientComponent">
         <implementation.java class="test.GreetingsServiceImpl"/>
         <reference name="helloWorldService" target="MyServiceComponent">
            <interface.wsdl interface="http://helloworld#wsdl.interface(HelloWorld)"/>
         </reference>
       </component>

</composite>
```

## Intra composite over SCA default binding

```
<?xml version="1.0" encoding="UTF-8"?>

   <composite xmlns="http://www.osoa.org/xmlns/sca/1.0" targetNamespace="http://mysca/samples"
         name="Service1Composite">

       <component name="HWServiceComponent">
         <implementation.java class="test.HelloWorldImpl"/>
         <reference name="component2Ref" target="Component2"/>
      </component>

        <component name="Component2">
        <implementation.java class="test.Component2Impl"/>
        </component>

   </composite>
```

## SCA Service with workManager specified for the service

```
<?xml version="1.0" encoding="UTF-8"?>

   <composite xmlns="http://www.osoa.org/xmlns/sca/1.0"  xmlns:wm="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
         targetNamespace="http://mysca/samples" name="Composite2">

      <component name="Component2">
        <service name="OneWayService">
          <!-- This service uses the @oneway annotation to specify this operation only has an input message
                and no output message.   -->
           <wm:workManager value="wm/scatest"/>
```

```
        <!-- This service specifies a workManager where the jndiName is wm/scatest. -->
      </service>
      <implementation.java class="test.Component2Impl"/>
      <reference name="component3" target="Component3"/>
    </component>

    <!-- component service with @oneway (non blocking operation -->
    <component name="Component3">
      <!-- By not defining the workManager, the SCADefaultWorkmanager that is created by the SCA
           runtime environment is used here. -->
      <implementation.java class="test.Component3Impl"/>
    </component>

  </composite>
```

## What to do next

Deploy the SCA component or application.

## Configuring Java serialization for the SCA default binding

You can convert objects to a wire format, or *serialize* the objects, before transmitting them. You can serialize objects for applications that use the Service Component Architecture (SCA) default binding.

### About this task

When using the default binding, objects are serialized to one of several wire formats before being sent. By default, objects are serialized to XML and sent as text over the wire. However, XML serialization occurs only with classes that are JAXB serializable. These classes require a default, no-argument constructor as well as getter and setter methods for each field.

To use non-JAXB serializable objects, you must specify a different wire format in the composite definition file. Specify the default binding element `wireFormat.javaObject` as a child element.

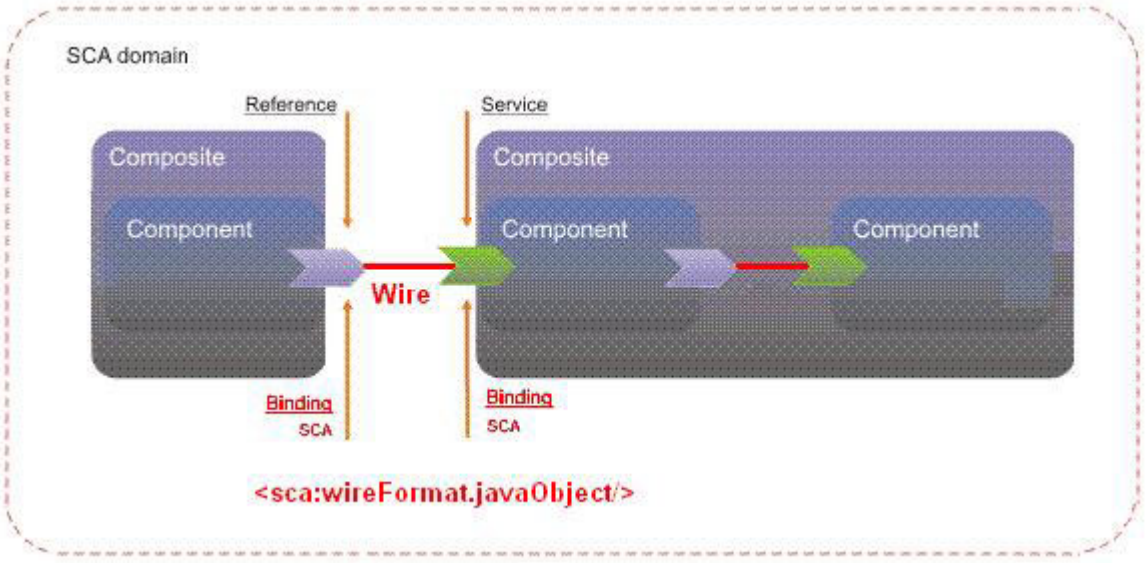

*Figure 1. For non-JAXB serializable objects, use the wire format javaObject for the SCA default binding*

When `wireFormat.javaObject` is used, objects use Java serialization instead of XML and travel as a stream of bytes over the wire. This enables you to use, for example, non-JAXB serializable Enterprise JavaBeans with the default binding.

### Procedure

1. Open an editor on the composite definition file for your SCA application.
2. Add Java serialization in the default binding of the composite definition file.
   a. Add the product SCA namespace to the composite:
      ```
      <composite xmlns:sca="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06">
      ```
   b. For each service or reference `<binding.sca>` element, add a `wireFormat.javaObject` child element using that namespace:
      ```
      <sca:wireFormat.javaObject/>
      ```
3. Save the changes to the composite definition file.

### Results

You have configured Java serialization over the default bindings for your SCA service or reference.

Using the incorrect wire format might cause a runtime exception in your application.

### Example

The following composite definition file configures Java serialization in the SCA default binding:

```
<?xml version="1.0" encoding="UTF-8"?>

<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
      targetNamespace="http://scajavaserialize"
      xmlns:sca="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
      name="sca-java-serialize-backend">

  <component name="SCAJavaSerializationBackendComponent">
    <implementation.java class="test.bindings.sca.SerializeBackendImpl"/>

    <service name="SerializeBackendService">
      <interface.java
         interface="test.bindings.sca.SerializeBackendService"
         callbackInterface="test.bindings.sca.SerializeCallback">
      <binding.sca>
         <sca:wireFormat.javaObject/>
      </binding.sca>

      <callback>
         <binding.sca>
            <sca:wireFormat.javaObject/>
         </binding.sca>
      </callback>
    </service>

  </component>

</composite>
```

### What to do next

Deploy your SCA component in an application.

## Using the SCA default binding to find and locate SCA services

The product supports an API that you can use to find and invoke Service Component Architecture (SCA) services over the SCA default binding.

### About this task

According to the SCA Version 1.0 specification, you can only obtain a reference to an SCA service from another component that is statically wired to the service. However, you can use a service proxy to invoke the target service. This function requires a WebSphere Application Server base or network deployment topology with at least one server that supports SCA composites. Also, SCA service must be deployed, running, and accessible over the default binding, `<binding.sca>`. There is no support for a domain URI, so all requests go to the default domain at the cell level. Using this API enables code that is not an SCA component to use the SCA client programming model.

### Procedure

Use the import method in your client code to locate an SCA service.
The following method is supported for client code to locate a service that is deployed onto a cell:

```
import com.ibm.websphere.sca.context.CurrentCompositeContext;
import com.ibm.websphere.sca.context.CompositeContext;
CompositeContext compositeContext = CurrentCompositeContext.getContext();
EchoService echoService = (EchoService) compositeContext
 .getService(EchoService.class, "SCASimpleEchoService");
```

### What to do next

To improve the component performance, make the caller of the `compositeContext.getService()` API cache the SCA default binding service proxy that is obtained from `compositeContext.getContext()`. Caching `echoService` in the example can avoid calls to the service registry for subsequent requests, resulting in better performance.

## Configuring the SCA web services binding

You can expose a Service Component Architecture (SCA) application as a web service by configuring the SCA web services binding.

### About this task

Web services technology plays an important role in most service-oriented architecture (SOA) solutions relevant today, including SCA. The web service binding type enables SCA applications to expose services as web services to external clients and gives SCA components access to external web services. External clients that access SCA services exposed as web services might or might not be implemented as an SCA component. You can use the web service binding element `<binding.ws>` within either a component service or a component reference definition. When this binding is used with a component service, the web service binding type enables clients to access a service that is offered by a particular component as a web service. If the web service binding is used with a component reference, components in an SCA composite can consume an external web service and access it like any other SCA component.

The product supports Web Services Description Language (WSDL) Version 1.1 definitions that also conform to the WS-I Basic Profile Version 1.1 and Simple SOAP Binding Profile 1.0 standards, and use the document literal style. All these conditions are required for support.

The SCA web services binding applies to the services and references of components. The web service binding defines the manner in which a service is made available as a web service, and in which a reference can invoke a web service. This binding is a WSDL-based binding; meaning that the binding either references an existing WSDL document or enables you to specify enough information to generate a WSDL document.

You can typically use the same policy set functionality, that you use for defining qualities of service on JEE-based web services that are running in the application server, to define quality of service definitions on SCA clients and services that use the SCA web service binding. When the instructions for

administratively configuring these policy set definitions are different for SCA-based web services than they are for Java EE-based web services, then special topics and instructions are provided in this information center. If there are no special instructions for SCA, configure the corresponding quality of service on the SCA-based web service the same way that you would configure that quality of service for a Java EE-based web service.

**Note:** The SCA web services binding provides support for providing and consuming services using the SOAP Version 1.1 over HTTP and SOAP V1.2 over HTTP protocols.

**Note:** The product does not support the following functions:

- Java API for XML-Based Web Services (JAX-WS) handlers when using the SCA web services binding
- Message Transmission Optimization Mechanism (MTOM) or SOAP with Attachments (SwA) binary message optimizations

Use the SCA web services binding without implementing JAX-WS handlers. Do not use SwA binary message optimizations or MTOM optimizations for transferring binary data between SCA clients and services that use the SCA web services binding. Instead of implementing MTOM or SwA binary message optimizations to send binary data, use the base64Binary XML Schema Definition (XSD) encoding to embed the data within the SOAP message.

## Procedure

- Configure an SCA service with the SCA web services binding.

  Depending on whether you develop your SCA service using the top-down development approach starting with an existing WSDL file or you develop your SCA service using the bottom-up development approach starting with existing Java code, you might or might not have a WSDL file available. Additionally, the WSDL file might define only a portType or it might include a port definition as well.

  – For SCA applications that are developed top-down starting from a WSDL port, you must refer to the port definition in the existing WSDL file by adding a <binding.ws> element as a child of your <service> element. An example of the syntax for this step follows:

```
<binding.ws wsdlElement="<port target Namespace>#wsdl.port(<service name attr>/<port name attr>)"/>
```

    The location attribute of the <address> element for the port is ignored by the runtime environment in determining the URL at which your service is invoked.

    The following example demonstrates the relationship between the WSDL file and the composite definition for this scenario:

    WSDL file

```
<wsdl:definitions targetNamespace="http://www.ibm.com/" xmlns:tns="http://www.ibm.com/" ...>
      ....
     <wsdl:portType name="MyPortType ">
      ....
     <wsdl:binding name="MyBinding" type="tns:MyPortType">
      ....
     <wsdl:service name="MyService">
         <wsdl:port binding="tns:MyBinding" name="MyPort">
             <wsdlsoap:address location=""/>
         </wsdl:port>
     </wsdl:service>
```

    Composite definition

```
<composite...>
     <component name="MyComponent">
       <implementation.java class="test.MyCompImpl"/>
         <service name="GuessAndGreetWrapped">
             <interface.wsdl interface="http://www.ibm.com/#wsdl.interface(MyPortType)" />
             <binding.ws wsdlElement="http:// www.ibm.com/#wsdl.port(MyService/MyPort)" />
         </service>
     </component>
      ...
</composite>
```

  – For SCA applications that are developed top-down starting from a WSDL portType, you must create an empty <binding.ws> element as the child of your <service> element. Creating the empty

<binding.ws> element directs the runtime environment to generate a port that corresponds to your WSDL portType definition. The generated port uses a SOAP 1.1 over HTTP WSDL binding.

The following example demonstrates the relationship between the WSDL file and the composite definition for this scenario:

WSDL file

```
<wsdl:definitions targetNamespace="http://www.ibm.com/" xmlns:tns="http://www.ibm.com/" ...>
      ....
     <wsdl:portType name="MyPortType ">
```

Composite definition

```
<composite...>
     <component name="MyComponent">
       <implementation.java class="test.MyCompImpl"/>
         <service name="GuessAndGreetWrapped">
             <interface.wsdl interface="http://www.ibm.com/#wsdl.interface(MyPortType)" />
             <binding.ws/>
         </service>
     </component>
      ...
</composite>
```

– For SCA applications that are developed bottom-up starting from existing Java code, you must create an empty <binding.ws> element as the child of your <service> element. Creating the empty <binding.ws> element directs the runtime environment to generate a WSDL portType that corresponds to your Java interface, and a port with a SOAP 1.1 over HTTP WSDL binding.

The following example demonstrates the <binding.ws> element within the composite definition for this scenario:

Composite definition

```
<composite...>
     <component name="MyComponent">
       <implementation.java class="test.MyCompImpl"/>
         <service name="GuessAndGreetWrapped">
             <binding.ws/>
         </service>
     </component>
      ...
</composite>
```

- Test the endpoint for your deployed SCA service.

  After you configure the SCA service with an SCA web services binding, you can test the endpoint for your deployed SCA service. With one exception, the URL format for the endpoint is the following:

  `http://<host>:<port_of_default_host>/Component_name/Service_name`

  For SCA services that are configured using `wsdlElement#wsdl.service`, the ports are appended; for example:

  `http://<host>:<port_of_default_host>/Component_name/Service_name/Port_name`

  Accessing the endpoint with a web browser displays the Axis2 cover page.

- View WSDL or XSD documents for the SCA service with the web service binding.

  Append the query string `?wsdl` to the endpoint URL. Accessing the URL with a web browser returns the outermost WSDL. You can then view included and imported documents using relative URLs.

- Configure an SCA reference (client) with an SCA web services binding.

  1. Configure the reference with an <interface.wsdl> element that refers to the portType of the target service. After you have obtained a WSDL portType from the web services provider, you can configure the <interface.wsdl>. Read about developing SCA service clients to learn how to configure the reference with an <interface.wsdl>.
  2. Resolve the SCA reference to an actual endpoint of a deployed web service using one of the mechanisms provided by the SCA web services binding support.
     – When the target web service is deployed as an SCA component service in the same domain as the client component, you can resolve the reference to the target component using the <reference> @target attribute. Using this attribute eliminates the need to know the specific URL of the deployed target service. For example:

```
<!-- The composite definition for the target service. -->
    <component name="TargetComponent">
      <implementation.java .../>
```

```
        <service name="MyService">
            <interface.wsdl ... />
            <binding.ws ... />
         </service>
     </component>

<!– The composite definition for the client when the client is in same SCA domain as the target component. -->
    <component name="ClientComponent">
      <implementation.java .../>

        <!-- Resolution done using the @target annotation. -->
        <reference name="myRef" target="TargetComponent/MyService">
             <interface.wsdl ... />

             <!-- The binding does not need endpoint-related info added. -->
             <binding.ws/>
        </reference>
     </component>
```

– If the target web service is not an SCA service in the same domain as the client, you must use a binding-specific endpoint resolution mechanism. You can also resolve a reference to an SCA service in the same domain by using the binding-specific mechanisms, instead of using the @target annotation.

a. You can define the endpoint for a deployed web service in an existing WSDL file that is obtained from a service provider. In this case, the client composite definition refers to the WSDL port of the target service which also specifies the endpoint from the <wsdlsoap:address> @location attribute. For example:

```
<wsdlsoap:address location="http://host:port/ComponentName/ServiceName"/>
```

The client points to the WSDL port using a @wsdlElement attribute on the <binding.ws> element using the following syntax:

```
<port target Namespace>#wsdl.port(<service name attr>/<port name attr>)"/>
```

The following example WSDL and composite definitions illustrate defining an endpoint for a deployed web service.

```
<!-- An example WSDL file.   -->

<wsdl:definitions targetNamespace="http://my.work/test/"
        xmlns:wsdl="http://schemas.xmlsoap.org/wsdl/"
    xmlns:wsdlsoap="http://schemas.xmlsoap.org/wsdl/soap/"   ... >
    <wsdl:service name="MyService">
      <wsdl:port binding="..." name="MyPort">
        <wsdlsoap:address
           location="http://www.mywork.com:9080/TargetComponent/MyService "/>
     </wsdl:port>
   </wsdl:service>
</wsdl:definitions>

<!-- An example composite definition.   -->
     <component name="ClientComponent">
      <implementation.java .../>
        <reference name="myRef">
           <interface.wsdl ... />
           <binding.ws wsdlElement="http://my.work/test/#wsdl.port(MyService/MyPort)"/>
        </reference>
     </component>
```

b. You can add the endpoint to the composite definition when the endpoint is not present in the WSDL file. In this case, add the @uri attribute to the <binding.ws> element to specify the endpoint.

```
<!-- An example WSDL file.   -->

<wsdl:definitions targetNamespace="http://my.work/test/"
        xmlns:wsdl="http://schemas.xmlsoap.org/wsdl/"
    xmlns:wsdlsoap="http://schemas.xmlsoap.org/wsdl/soap/"   ... >
    <wsdl:service name="MyService">
      <wsdl:port binding="..." name="MyPort">

        <!-- Here, the endpoint not specified in the WSDL. -->
         <wsdlsoap:address   location=""/>
     </wsdl:port>
   </wsdl:service>
</wsdl:definitions>

<!-- An example composite definition.   -->
     <component name="ClientComponent">
      <implementation.java .../>
        <reference name="myRef">
             <interface.wsdl ... />
```

```
            <binding.ws wsdlElement="http://my.work/test/#wsdl.port(MyService/MyPort)"
            uri="http://www.mywork.com:9080/TargetComponent/MyService" />
        </reference>
    </component>
```

- (optional) If your service or reference interface is bidirectional such that a callback is defined, you must also configure the web service binding on the callback.
  - Configure callback for your SCA web services binding using the WSDL port.

    Configuring callback for your SCA web services binding is similar to configuring an SCA service with the SCA web services binding; however, you add a second service, the callback. When you configure an SCA service with the SCA web services binding, you define a WSDL port, either explicitly by pointing directly to a WSDL port definition, or implicitly by giving the runtime enough information to calculate a WSDL port. Similarly, you must also define a WSDL port for the callback. A difference for the callback is that the runtime environment defines the WSDL port that is used for the callback because the runtime environment must keep this port tightly coupled to the forward call. Therefore, the most you can do when developing your SCA application using the top-down approach and defining a callback for this service, is to point to a WSDL binding. For example:

```
<!-- Configuring a service with callback with web service binding -->
     <component name="HelloWorldServiceComponent">
           <implementation.java class="..." />
           <service name="HelloWorldService">
                <interface.wsdl interface="http://www.ibm.com/sca/#wsdl.interface(HelloWorld)"
                     callbackInterface=" http://www.ibm.com/sca/#wsdl.interface(HelloWorldCallback)"/>
                <binding.ws wsdlElement="http://www.ibm.com/sca/#wsdl.port(HelloWorldService/HelloWorldSoapPort)"/>
                <callback>
                    <binding.ws wsdlElement="http://www.ibm.com/sca/#wsdl.binding(HelloWorldCallbackSoapBinding)" />
                </callback>
           </service>
    </component>
```

    The following example shows a configuration of a client component with reference to this service with callback defined. The reference and service configuration each share the same view of which direction is the forward direction and which is the callback direction.

```
<!-- Configuring a reference with callback with web service binding. -->
     <component name="HelloWorldClientComponent">
           <implementation.java class="..." />
           <reference name="helloWorldRef">
                <interface.wsdl interface="http://www.ibm.com/sca/#wsdl.interface(HelloWorld)"
                 callbackInterface=" http://www.ibm.com/sca/#wsdl.interface(HelloWorldCallback)"/>
           <binding.ws wsdlElement="http://www.ibm.com/sca/#wsdl.port(HelloWorldService/HelloWorldSoapPort)"/>
           <callback>
               <binding.ws wsdlElement="http://www.ibm.com/sca/#wsdl.binding(HelloWorldCallbackSoapBinding)" />
           </callback>
         </service>
    </component>
```

  - Configure callback for your SCA web services binding using the WSDL portType.

    Similar to the scenario of configuring a service with a web service binding when starting with a WSDL port, you also configure an empty <binding.ws> element to configure callback using the WSDL portType. The following composite definition example illustrates the scenario when starting with two WSDL portType definitions that has such that one interface uses a forward direction and the other interface uses callback:

```
<!-- Configuring a service with callback with web service binding -->
     <component name="HelloWorldServiceComponent">
           <implementation.java class="..." />
           <service name="HelloWorldService">
               <interface.wsdl interface="http://www.ibm.com/sca/#wsdl.interface(HelloWorld)"
                callbackInterface=" http://www.ibm.com/sca/#wsdl.interface(HelloWorldCallback)"/>
               <binding.ws/>
               <callback>
                  <binding.ws/>
               </callback>
           </service>
    </component>

<!-- Configuring a reference with callback with web service binding -->
     <component name="HelloWorldClientComponent">
           <implementation.java class="..." />
           <reference name="helloWorldRef">
              <interface.wsdl interface="http://www.ibm.com/sca/#wsdl.interface(HelloWorld)"
               callbackInterface=" http://www.ibm.com/sca/#wsdl.interface(HelloWorldCallback)"/>
              <binding.ws/>
              <callback>
                <binding.ws/>
              </callback>
           </service>
    </component>
```

– Configure callback for your SCA web services binding using the Java interface.

  For the bottom-up case starting with a Java interface, the composite definition is identical to the WSDL port and portType scenarios, except that you must replace the <interface.wsdl> elements with the <interface.java> element. For example:

```
<interface.java interface="helloworld.HelloWorldService"
        callbackInterface="helloworld.HelloWorldCallback"/>
```

## Results

You have a configured SCA web services binding service or reference.

**Note:** There are additional ways for the web service binding function to generate a WSDL port that are not described in this topic. However, these additional methods that rely on WSDL generation at run time add dependencies on the runtime environment that can cause problematic results.

For an example that is not problematic, suppose you write a service using the bottom-up style, starting from a Java interface, and deploy the service with an empty element. This directs the runtime environment to generate the WSDL port for this service. Also suppose an SCA client is developed with access to the original Java classes used to write the service implementation. This SCA client is used to test the SCA service using a client-side reference with web service binding. You can configure this reference without any knowledge of the service WSDL. In this case, the reference interface is the original Java interface of the service, and you can resolve the reference using the <reference> @target mechanism. See the resolving SCA references documentation for more information about using the <reference> element to resolve an SCA reference using the @target attribute. Using this approach, there is no WSDL to obtain or refer to in constructing the client. This works because the product runtime environment maps the service-side Java to WSDL in an identical manner as it maps the client-side Java to WSDL.

In contrast, the following scenario is problematic. Suppose that you write an SCA client with a web service binding reference to a web service that is hosted on a platform other than the product. It might seem reasonable to generate your Java client from the service provider, and then ignore the WSDL from that point on, avoiding the additional syntax in your client-side composite definition. To do this, you use the <binding.ws> element @uri attribute to specify the endpoint URL where the service is hosted. This scenario is problematic because it forces the runtime environment to generate a WSDL port for the client which might result in subtle mismatches between the WSDL generated for the client side and the actual WSDL port description of the deployed web service.

You can avoid these potential problems by ensuring that client package references the original WSDL obtained from a web service provider. If you use the shortcut of omitting a client-side reference to the WSDL, be sure to do so only in the case when you are sure the WSDL port that is generated for the client is identical to the WSDL port of the deployed service because the service port is generated using the same algorithm.

## What to do next

Deploy your composite that has the SCA web services binding service or reference.

**Note:** If the composite uses a bidirectional interface as an SCA service interface and a NullPointerException results when you add your SCA module or application to a business-level application (for example, using the wsadmin AdminTask.addCompUnit command), you might need to add the SCA @Callback annotation to the forward Java interface.

A NullPointerException can occur whether you are using a top-down development style (starting from WSDL or XSD) or a bottom-up style (starting from Java). With the top-down style, a composite definition typically includes a bidirectional interface definition such as the following:

```
<interface.wsdl interface="http://forward.my/intf#wsdl.interface(ForwardIntf)"
    callbackInterface="http://callback.my/intf#wsdl.interface(CallbackIntf)"/>
```

With the bottom-up style, a composite definition typically includes a bidirectional interface definition such as the following:

```
<interface.java interface="my.forward.intf.ForwardIntf"
    callbackInterface="my.callback.intf.CallbackIntf"/>
```

The NullPointerException can occur if the forward Java interface is not annotated with @Callback, or more specifically @org.osoa.sca.annotations.Callback. In the top-down example, the forward Java interface is the class generated from portType, `http://forward.my/intf/ForwardIntf` using the wsimport tool or `my.forward.intf.ForwardIntf` if the default options are used. In the bottom-up example, the forward Java interface is the class `my.forward.intf.ForwardIntf`.

To fix the NullPointerException problem, add the @Callback annotation to the forward Java interface and recompile. The @Callback annotation is a class-level annotation with a single argument, the callback interface Class object; for example:

```
...
import org.osoa.sca.annotations.Callback
@Callback(my.callback.intf.CallbackIntf.class)
public interface ForwardIntf  {
...
```

If you are using the recommended top-down development style, the forward Java interface is a generated class. It is generated from the WSDL portType using the wsimport tool. Use the `-s` or `-keep` option so that wsimport generates the Java source files, and then add the @Callback annotation manually to the generated class and recompile.

## Configuring web service binding custom endpoints to support a proxy server

You can configure SCA composites that are accessed by Hypertext Transfer Protocol (HTTP) for custom service endpoints using web services bindings.

### Before you begin

Before you begin this task, install your Service Component Architecture (SCA) application.

### About this task

When a service is exposed over the SCA web services binding, the service endpoint is specific to the server in which the service is hosted. Clients use this endpoint URI to access the service. In some cases, you may want clients to indirectly reference the service by using a proxy server as the service endpoint. For example, a proxy server is required to implement clustered web service binding endpoints. To enable clients to use a proxied endpoints, there are two ways to do this:

- If your endpoints are specified in the SCA contributions composite definition or WSDL document location attribute, you must specify the proxy server endpoint instead of the WebSphere server specific endpoint.
- If your client resolves the endpoint by using the <reference target=""> attribute in your client composite definition, use the administrative console to configure the custom endpoints for SCA composites that are accessed by the Hypertext Transfer Protocol (HTTP) protocol. This approach is the most flexible for SCA clients within the same domain as their service providers. When using <reference target=""> attribute, SCA references can resolve the service endpoints without the client specifying endpoints in the composite definition or WSDL document.

### Procedure

1. In the administrative console, click **Applications** > **Application Types** > **Business-level applications** > ***application_name*** > ***composition_unit_name*** > **Provide HTTP endpoint URL information**.
2. Select the HTTP endpoint URL prefix.

When entering custom endpoints, specify one and only one endpoint URL prefix each for the HTTP and HTTPS protocols.

### Results

You have configured web services bindings custom endpoints.

### What to do next

You can configure the bindings to do transport layer authentication.

## Configuring the SCA web services binding to transport SOAP messages over JMS

You can configure a Service Component Architecture (SCA) web service binding to transport SOAP messages over Java Message Service (JMS) protocol.

### Before you begin

For information about web service bindings, read “Configuring the SCA web services binding” on page 1055.

### About this task

Web services technology plays an important role in most service-oriented architecture (SOA) solutions relevant today, including SCA. The web service binding type enables SCA applications to expose services as web services to external clients and gives SCA components access to external web services. Using JMS as a transport for Web services provides a reliable asynchronous messaging transport for request and response.

This topic describes how to configure a web service binding to flow SOAP messages over JMS.

**Note:** The web service binding supports Web Services Description Language (WSDL) Version 1.1. Further, the web service binding supports industry standard SOAP/JMS protocol and IBM proprietary SOAP over JMS protocol.

### Procedure

1. Identify and configure JMS resources using the administrative console or the wsadmin scripting tool.

   Refer to topics on creating JMS resources based on different JMS providers.

   For example, to identify and configure JMS resources based on the default JMS provider, do the following:

   a. Create a service integration bus and associate a bus member.
   b. Create destinations for the request and response for the service integration bus.
   c. Create destinations for the request and response under JMS resources.
   d. Create an activation specification that is associated with a request destination.
   e. Create connection factories to process the request and to send the response.
2. Configure an SCA service with an SCA web services binding to transport SOAP messages over JMS.

   Configure a Web service binding as described in “Configuring the SCA web services binding” on page 1055 with three additional attributes under the `<binding.ws>` element to use a JMS transport:

   - Web service binding endpoint `uri` attribute
   - `@activationSpec` attribute
   - Response `@responseConnectionFactory` attribute

   a. Open an editor on the SCA composite definition file that specifies an SCA service with a web service binding.

b. In the composite definition file, configure the web service binding endpoint `uri` attribute.

Specify the uniform resource identifier (URI) in SOAP over JMS endpoint uniform resource locator (URL) syntax. A JMS endpoint URL accesses web services with a JMS transport. The URL specifies the JMS destinations, connection factory, and port component name for the web service request.

Specify the URI in syntax that supports either of the following protocols:
- Industry standard SOAP/JMS protocol (recommended)
- IBM proprietary SOAP over JMS protocol (deprecated)

**URI based on industry standard SOAP over JMS protocol**

The syntax for a URI based on industry standard SOAP over JMS protocol is as follows:

```
uri=jms:jndi:<destination_JNDI_name>?<property>=<value>&<property>=<value>& ...
```

The URL consists of the `jms:` transport type, followed by the `jndi:` variant type, followed by the Java Naming and Directory Interface (JNDI) name of the destination queue or topic, followed by the query string containing a list of property and value pairs that specify JMS endpoint information. The `jndi:` variant means that JNDI is used to locate object names in the endpoint URL string.

For *property*, you can specify URL properties such as the following:

*Table 133. JMS endpoint URL properties typically used for a URI based on industry standard SOAP over JMS protocol. The properties are jndiConnectionFactoryName, targetService, and replyToName.*

| Property name | Description |
|---|---|
| jndiConnectionFactoryName | Specifies the JNDI name of the connection factory that is used by the client run time to establish a connection to the JMS messaging engine. jndiConnectionFactoryName is optional for the service `uri` attribute. |
| targetService | Specifies the target service to which to deliver the message. For a forward call from a service to a reference, targetService has the format `serviceComponentName/serviceName`. In a callback `uri`, targetService has the format `referenceComponentName/referenceName`. |
| replyToName | Specifies the JNDI name of the JMS destination to which the response message is sent. replyToName is a JMS-related property that enables the client to use a previously defined, permanent queue rather than a temporary queue, for receiving replies. |

For a complete list of properties supported, refer to the topic on JMS endpoint URL syntax.

A URI based on industry standard SOAP over JMS protocol resembles the following:

```
uri="jms:jndi:jms/AccountServicetDestination?jndiConnectionFactoryName=jms/AccountServiceCF
&amp;replyToName=jms/AccountServiceResponse&amp;targetService=AccountServicePort"
```

**URI based on IBM proprietary SOAP over JMS protocol**

**Attention:** IBM proprietary SOAP over JMS protocol is deprecated.

The syntax for a URI based on IBM proprietary SOAP over JMS protocol is as follows:

```
uri=jms:/[queue|topic]?<property>=<value>&<property>=<value>& ...
```

The URL consists of the `jms:` transport type, followed by either `/queue` or `/topic` to specify the JMS destination type, followed by the query string containing a list of property and value pairs that specify the JMS endpoint information.

For *property*, you can specify URL properties such as the following:

*Table 134. JMS endpoint URL properties typically used for a URI based on IBM proprietary SOAP over JMS protocol. The properties are destination, connectionFactory, replyToDestination, and targetService.*

| Property name | Description |
|---|---|
| destination | Specifies the JNDI name of the destination queue or topic. |
| connectionFactory | Specifies the JNDI name of the connection factory. connectionFactory is optional for the service `uri` attribute. |
| replyToDestination | Specifies the JNDI name to which a response is sent. replyToDestination is optional for the service `uri` attribute. |
| targetService | Specifies the target service to which to deliver the message. For a forward call from a service to a reference, targetService has the format `serviceComponentName/serviceName`. In a callback `uri`, targetService has the format `referenceComponentName/referenceName`. |

For a complete list of properties supported, refer to the IBM proprietary SOAP over JMS protocol topic.

A URI based on IBM proprietary SOAP over JMS protocol resembles the following:

```
uri="jms:/queue?destination=jms/AccountServiceDestination&amp;connectionFactory=jms/AccountServiceCF
&amp;replyToDestination=AccountServiceResponse&amp;targetService=AccountServiceComponent/AccountService"
```

c. In the composite definition file, configure an `@activationSpec` attribute under the `<binding.ws>` element.

   The attribute identifies the activation specification that the service uses to connect to the JMS destination and to process incoming request messages.

   For the destination associated with this activation specification, specify the request destination defined in the Web service binding endpoint `uri`; for example:

   ```
   soapjms:activationSpec="jms/AccountActivationSpec"
   ```

   Qualify the composite by setting `xmlns="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"`.

d. In the composite definition file, configure a response `@responseConnectionFactory` attribute under the `<binding.ws>` element to send a response back to the client when request-response messaging pattern is used.

   For example:

   ```
   soapjms:responseConnectionFactory="jms/Account_Response_CF"
   ```

   Qualify the composite by setting `xmlns="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"`.

After these updates are made to the `<binding.ws>` element, the composite definition file resembles:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
 xmlns:soapjms="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
 targetNamespace="http://www.ibm.com/samples/sca/mybank"
 name="MyBank">
  <component name="AccountServiceComponent">
    <implementation.java
      class="samples.mybank.AccountServiceImpl"/>
    <service name="AccountService">
      <interface.wsdl
      interface=
          "http://www.mybank.com/account#wsdl.interface(AccountService)" />
      <binding.ws
          wsdlElement=
            "http://www.mybank.com/account#wsdl.port(AccountService/AccountServicePort)"

          uri=
            "jms:/queue?destination=jms/AccountRequestQueue&amp;connectionFactory=
             jms/Account_CF&amp;replyToDestination=jms/AccountResponseQueue&amp;targetService=AccountServiceComponent/AccountService"

          soapjms:activationSpec="jms/AccountActivationSpec"

          soapjms:responseConnectionFactory="jms/Account_Response_CF"/>
    </service>
  </component>
</composite>
```

3. Configure an SCA reference (client) with an SCA web services binding to transport SOAP message over JMS.

   Configure a web service binding with a web service binding endpoint `uri` attribute specific to JMS transport under the `<binding.ws>` element.

   a. Open an editor on the SCA composite definition file that specifies an SCA reference with a web service binding.

   b. In the composite definition file, configure the Web service binding endpoint `uri`.

      Specify the URI in SOAP over JMS endpoint URL syntax. The URL specifies the JMS destinations, connection factory, and port component name for the web service request. A JMS endpoint URL can be based on industry standard SOAP/JMS protocol (recommended) or on IBM proprietary SOAP over JMS protocol. For a description of the URI syntax, see step 2(b). In SOAP over JMS support for web service bindings, you must use the `<binding.ws>` `uri` attribute for endpoint resolution to the target component; you cannot use the SCA reference `@target` attribute.

      The URI resembles the following:

      ```
      uri="jms:/queue?destination=jms/AccountRequestQueue&amp;connectionFactory=jms/Account_CF
      &amp;replyToDestination=jms/AccountResponseQueue&amp;targetService=AccountServiceComponent/AccountService"
      ```

   After you define the URI in the `<binding.ws>` element, the composite definition file resembles:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
targetNamespace="http://www.ibm.com/samples/sca/mybank"
name="MyBankClient">
  <component name="AccountSummaryService">
    <implementation.java
      class="samples.mybank.AccountSummaryServiceImpl"/>
    <reference name="accountService">
    <interface.wsdl
      interface=
        "http://www.mybank.com/account#wsdl.interface(AccountService)" />
    <binding.ws
      wsdlElement=
        "http://www.mybank.com/account#wsdl.port(AccountService/AccountServicePort)"

       uri=
         "jms:/queue?destination=jms/AccountRequestQueue&amp;connectionFactory=
          jms/Account_CF&amp;replyToDestination=jms/AccountResponseQueue&amp;targetService=AccountServiceComponent/AccountService"/>
    </reference>
  </component>
</composite>
```

## Results

You have a configured an SCA web services binding service or reference.

## Examples

### Configuring a request-response Message Exchange Pattern for SOAP over JMS

This example describes a <binding.ws> element in the composite definition file for a request-response message exchange pattern from an SCA component reference to an SCA component service.

The following example shows an SCA component with a reference binding:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
           xmlns:soapjms="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
           targetNamespace="http://www.ibm.com/samples/sca/mybank" name="MyBankClient">
  <component name="AccountSummaryService">
    <implementation.java class="samples.mybank.AccountSummaryServiceImpl"/>
    <reference name="accountService">
      <interface.wsdl interface="http://www.mybank.com/account#wsdl.interface(AccountService)"/>
      <binding.ws
        wsdlElement="http://www.mybank.com/account#wsdl.port(AccountService/AccountServicePort)"
        uri="jms:jndi:jms/MyBankAccountService_Request?jndiConnectionFactoryName
          =jms/MyBankAccountService_CF&amp;replyToName=jms/MyBankAccountService_Response&amp;targetService
          =AccountServiceComponent/AccountService"/>
    </reference>
  </component>
</composite>
```

The following example shows an SCA component with a service binding:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
           xmlns:soapjms="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
           targetNamespace="http://www.ibm.com/samples/sca/mybank" name="MyBank">
  <component name="AccountServiceComponent">
    <implementation.java class="samples.mybank.AccountServiceImpl"/>
    <service name="AccountService">
      <interface.wsdl interface="http://www.mybank.com/account#wsdl.interface(AccountService)"/>
        <binding.ws
          wsdlElement="http://www.mybank.com/account#wsdl.port(AccountService/AccountServicePort)"
          uri="jms:jndi:jms/MyBankAccountService_Request?"
          soapjms:activationSpec="jms/MyBankAccountService_AS"
          soapjms:responseConnectionFactory="jms/MyBankAccountService_CF"/>
    </service>
  </component>
</composite>
```

You can use these composite definition examples for @OneWay Message Exchange Pattern. When using @OneWay, the reference binding URI does not need to specify `replyToName` because there is no reply for the @OneWay call.

### Configuring an SCA callback for SOAP over JMS

This example describes a `<binding.ws>` element in the composite definition file for a callback message exchange pattern between an SCA component reference and an SCA component service.

The following example shows an SCA component with a reference binding:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
           xmlns:soapjms="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
           targetNamespace="http://www.ibm.com/samples/sca/mybank" name="MyBankClient">
  <component name="AccountSummaryService">
    <implementation.java class="samples.mybank.AccountSummaryServiceImpl"/>
    <reference name="accountService">
      <interface.wsdl
         interface="http://www.mybank.com/account#wsdl.interface(AccountService)"
         callbackInterface="http://www.mybank.com/account#wsdl.interface(AccountServiceCallback)" />
      <binding.ws
         wsdlElement="http://www.mybank.com/account#wsdl.port(AccountService/AccountServicePort)"
         uri="jms:jndi:jms/MyBankAccountService_Request?jndiConnectionFactoryName
            =jms/MyBankAccountService_CF&amp;replyToName=jms/MyBankAccountService_Response&amp;
            targetService=AccountServiceComponent/AccountService"/>
       <callback>
         <binding.ws
            wsdlElement="http://http://www.mybank.com/account#wsdl.binding(AccountServiceCallback)"
            uri="jms:jndi:jms/MyBankAccountService_Callback?jndiConnectionFactoryName
             =jms/MyBankAccountService_CF&amp;replyToName=jms/MyBankAccountService_Response&amp;
             targetService=AccountServiceComponent/AccountService"
            soapjms:activationSpec="jms/$MyBankAccountService_Callback_AS"
            soapjms:responseConnectionFactory="jms/MyBankAccountService_CF"/>
       </callback>
    </reference>
  </component>
</composite>
```

`targetService` is the target service to which a message is delivered. In a forward call from a service to a reference, specify the targetService in the format *`serviceComponentName/serviceName`*. In the callback URI, specify the targetService in the format *`referenceComponentName/referenceName`*.

The following example shows an SCA component with a service binding:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
           xmlns:soapjms="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
           targetNamespace="http://www.ibm.com/samples/sca/mybank" name="MyBank">
  <component name="AccountServiceComponent">
    <implementation.java class="samples.mybank.AccountServiceImpl"/>
    <service name="AccountService">
      <interface.wsdl interface="http://www.mybank.com/account#wsdl.interface(AccountService)"
           callbackInterface="http://www.mybank.com/account#wsdl.interface(AccountServiceCallback)"/>
       <binding.ws
          wsdlElement="http://www.mybank.com/account#wsdl.port(AccountService/AccountServicePort)"
          uri="jms:jndi:jms/MyBankAccountService_Request?jndiConnectionFactoryName
           =jms/MyBankAccountService_CF&amp;replyToName=jms/MyBankAccountService_Response&amp;
           targetService=AccountServiceComponent/AccountService"
          soapjms:activationSpec="jms/MyBankAccountService_AS"
          soapjms:responseConnectionFactory="jms/MyBankAccountService_CF"/>
         <callback>
           <binding.ws
              wsdlElement="http://http://www.mybank.com/account#wsdl.binding(AccountServiceCallback)"/>
         </callback>
    </service>
  </component>
</composite>
```

The service binding callback element does not need to specify a JMS endpoint URI because the callback URI is derived from the reference binding.

In some examples, the `uri` value is shown on multiple lines for publication. In your composite definition, place the `uri` value on one line.

### What to do next

Deploy the SCA composite in an application and test the flow of messages over the web service binding.

## Configuring EJB bindings in SCA applications

Use this task to learn how to use Enterprise JavaBeans (EJB) bindings in SCA applications.

Support is provided for EJB bindings in 2.x and 3.x-style beans, for service, reference, and reference target.

The EJB bindings do not support `interface.wsdl` files.

The following is an example of an composite definition that has a service exposed over an EJB 3.x binding:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0" targetNamespace="http://neworder/sca/jdbc"
name="NewOrderComposite">

<component name="NewOrderEJB3ServiceComponent">
<implementation.java class="neworder.sca.jdbc.NewOrderServiceImpl" requires="managedTransaction.local"/>
<service name="NewOrderService" requires="suspendsTransaction">
<interface.java interface="neworder.sca.jdbc.NewOrderService"/>
<binding.ejb ejb-version="EJB3"/>
</service>
</component>
</composite>
```

A client that wants to invoke the resultant enterprise bean would treat it like any other enterprise bean and not like a regular SCA service. CompositeContext.getService is not supported for a non-SCA binding, therefore, a getService() on the CompositeContext would not work here. The following is the client code for the previous example:

```
InitialContext ctxt = new InitialContext();
  Object remoteObj = ctxt.lookup("ejb/sca/ejbbinding/NewOrderEJB3ServiceComponent/NewOrderService#neworder.sca.jdbc.NewOrderServiceRemote");
  NewOrderServiceRemote newOrderRemote = (NewOrderServiceRemote) PortableRemoteObject.narrow(remoteObj, NewOrderServiceRemote.class);
```

The following is an example of an composite definition that contains references to both EJB 2.x and EJB 3.x bindings:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
targetNamespace="http://erww.workload" name="ConvertComposite">

<component name="ConvertInputOutputServiceComponent">
<implementation.java class="convert.inputoutput.sca.ConvertInputOutputServiceImpl"

<reference name="priceQuoteSessionReference">
<interface.java interface="priceQuoteSession.PriceQuoteSession"/>
<binding.ejb uri="corbaname:iiop:localhost:2809/NameServiceServerRoot#ejb/session/PriceQuoteSessionFacadeBean"/>
</reference>
</component>
</composite>
```

Different binding.ejb attributes can be used for service side EJB bindings or reference side EJB bindings. The following information explains how the default value is calculated for each side:

## Service side

The service side EJB binding applies only to Java archive (JAR)-packaged SCA applications.

**EJB 2.0-level beans**

URI is the JNDI name for the home; it can be calculated with the default short name in the following form:

`/sca/ejbbinding/`*`component_name`*`/`*`service_name`*

Therefore, the URI can be calculated as:

`corbaname:iiop:localhost:2812/NameServiceServerRoot#ejb/sca/ejbbinding/`*`component_name`*`/`*`service_name`*

You can use it to look up home.

**EJB 3.x-level beans**

The URI contains the component-id, therefore, it is calculated the same as the EJB 2.0 beans as follows:

`sca/ejbbinding/`*`component_name`*`/`*`service_name`*

The URI can be calculated as:

`corbaname:iiop:localhost:2812/NameServiceServerRoot#ejb/sca/ejbbinding/`*`component_name/service_name#package.qualified.interface of SCA Java interface with prefix of Remote or Local to the class name`*

You can use it directly to get the business interface.

The following code example displays as if it were a session bean:

```
<session name="ServiceNameBean" component-id="sca/ejbbinding/component_name/service_name"/>
```

When an SCA service is exposed through an EJB service binding, the service is exposed through an enterprise bean. During deployment, the SCA runtime generates a session bean for the service exposed through the EJB binding. The caller of the composite service can invoke this service by accessing the generated enterprise bean as if they are invoking any enterprise bean.

The generated enterprise bean for the composite service is in the directory, *profile_root*`/installedApps/`*`cell_name`*`/`*`composite_name`*`.ear/`. Callers need to include the client required classes, such as remote or home, of the generated bean in the classpath or bundle the classes in the JAR file.

## Reference side

The reference side EJB binding applies to both JAR-packaged applications and web application archive (WAR)-packaged applications, if not otherwise stated.

- The URI is used to lookup either the EJB 2.x home or EJB 3.x business interface. Follow the naming convention of the Java Enterprise Edition (JEE) specification if you are using an existing JEE EJB module. If you use an SCA service with the binding.ejb attribute, use the value mentioned above. For more information about the EJB 3.x JNDI name, see the topic EJB 3.x bindings overview.
- homeInterface: Not used
- ejb-link-name: Only applies to WAR-packaged SCA applications. When URI is not defined, use it to look up an EJB module that is defined in the same enterprise archive (EAR) as the WAR.
- session-type: default value "stateless"
- ejb-version: default value "EJB2"

**Attention:** A lookup issue for EJB 3.x reference bindings might occur when the URI follows the corbaname:iiop:host:port/NameServiceServerRoot##*ejb3_binding_longform* pattern This problem exists only for EJB 3.x reference bindings. When the EJB 3.x reference binding URI follows the corbaname:iiop:host:port/NameServiceServerRoot##*ejb3_binding_longform* pattern, where *ejb_binding_longform* is ejb/<component-id#<package.qualified.interface>, and if more than one enterprise bean that is implementing the same interface is deployed on that server, lookup may not be directed to the correct EJB with corresponding component ID.

An example of a URI where this problem can occur is as follows:

```
uri="corbaname:iiop:host:port/NameServiceServerRoot#ejb/EJB3CounterSample/EJB3Beans.jar
/StatelessCounterBean#com.ibm.websphere.ejb3sample.counter.RemoteCounter
```

There are two enterprise beans implementing the com.ibm.websphere.ejb3sample.counter.RemoteCounter interface. To avoid this issue:

- Use a URI that does not start with "corbaname:"
- Use a binding name in the URI that is an EJB binding short form, for example, corbaname:iiop:host:port/NameServiceServerRoot#<package.qualified.interface>.
- Use a binding name in the URI that is a unique user-defined binding name.
- Ensure that the two enterprise beans that are deployed on the server do not implement the same interface.
- Ensure that the EJB binding URI is pointing to an EJB 2.0 bean.

To resolve this problem, follow these guidelines:

- If the EJB reference binding is accessing an enterprise bean that is located in the same cell, the URI should not start with "corbaname:."
- For same cell lookup, the URI pattern should be one of the following.

  ```
  uri="ejb/EJB3CounterSample/EJB3Beans.jar/StatelessCounterBean#com.ibm.websphere.ejb3sample.counter.RemoteCounter"
  ```

  or

  ```
  uri="cell/clusters/cluster_name/ejb/EJB3CounterSample/EJB3Beans.jar
  /StatelessCounterBean#com.ibm.websphere.ejb3sample.counter.RemoteCounter"
  ```

  or

  ```
  uri="cell/nodes/node_name/servers/server_name//ejb/EJB3CounterSample/EJB3Beans.jar
  /StatelessCounterBean#com.ibm.websphere.ejb3sample.counter.RemoteCounter"
  ```

- Even in cross cell access, the recommended method is to create a namespace binding for the enterprise bean that is accessed by the EJB reference binding. After the namespace binding is created, use the namespace binding in the URI of the EJB reference binding as uri="cell/persistent/*name_in_namespace_binding*".

Different patterns of the SCA EJB reference binding URI are based on the user setup and configurations. If the SCA EJB reference binding is accessing a stateless session bean on the same server, the EJB reference binding URI can be designated as the JNDI name, uri="ejb/com/app/resumebank/ResumeBankHome". If the SCA EJB reference binding is referencing another SCA service with an EJB binding in the same server, the URI can be designated as the JNDI name, uri="ejb/com/app/resumebank/ResumeBankHome" or you can use the *reference target=componentName/serviceName* instead of the URI.

If the EJB reference binding is accessing a stateless session bean that is deployed in the same cell, the URI can be based on cluster/node/server setup, for example:

```
uri="cell/clusters/cluster2/ejb/com/app/resumebank/ResumeBankHome"
uri="cell/nodes/node_name/servers/server_name/ejb/com/app/resumebank/ResumeBankHome"
```

If the EJB reference binding is accessing a stateless session bean on a different cell (cross cell) or a mixed cell, you need to create a namespace binding, either an enterprise bean or Corba type, in the administrative console and use the name in namespace binding in EJB reference binding URI such as,

uri="cell/persistent/*name_in_namespace_binding*". For example, uri="cell/persistent/*neworder*" where *neworder* is name in the namespace binding.

## Using EJB bindings in SCA applications in a cluster environment

Use this task to learn how to use Enterprise JavaBeans (EJB) bindings that are deployed in Service Component Architecture (SCA) applications in a cluster environment.

### Service side

When an SCA service is exposed with a binding.ejb element, the service is exposed through an enterprise bean. During deployment, the SCA runtime generates a session bean for the service that is exposed through EJB binding. The caller of the composite service can invoke this service by accessing the generated EJB.

If the service is exposed through an EJB 2 bean, the EJB is bound at:

ejb/sca/ejbbinding/*component_name*/*service_name*

For example:

ejb/sca/ejbbinding/CompanyComponent/Company

If the service is exposed through an EJB 3.x bean, the EJB is bound at:

ejb/sca/ejbbinding/*component_name*/*service_name#fullyQualifiedServiceInterfaceName*Remote

For example:

ejb/sca/ejbbinding/CompanyComponent/Company#com.app.jobbank.CompanyRemote

The generated EJB for the composite service will be under *profile_root*/installedApps/*cell_name*/*composite_name*.ear/.

Callers need to include client required classes (such as remote or home) of this generated bean in their classpath (or bundle the classes in their JAR file).

Lookup and invoke of this generated service EJB from a clustered environment is the same as lookup and invoke of any EJB in a product clustered setup. Refer to "Naming considerations in clustered and cross-server environments" in the *EJB 3.x application bindings overview* topic.

### Reference side

When used on the reference side, the binding.ejb element should specify a URI attribute with values that match the value that is typically used when an EJB client calls the initialContext.lookup() method. The general convention is:

"corbaname:iiop:*host*:*port*/NameServiceServerRoot#*JNDI_name*"

where *JNDI_name* is the JNDI name of the target EJB.

For example:

uri="corbaname:iiop:localhost:2809/NameServiceServerRoot#ejb/session/PriceQuoteSessionFacadeBean"

JNDI name syntax differs if the target EJB is an EJB 2 or EJB 3.x bean.

When the referred EJB service is in a different cell, the URI might resemble one of the following:

uri="corbaname:iiop:localhost:2809/NameServiceServerRoot#cell/clusters/cluster1/ejb/session/PriceQuoteSessionFacadeBean"

or

uri="corbaname::/NameServiceServerRoot#cell/clusters/cluster1/ejb/session/PriceQuoteSessionFacadeBean"

or

```
uri="cell/clusters/cluster1/ejb/session/PriceQuoteSessionFacadeBean"
```

if the target EJB is on the same machine but on different cluster.

In advanced scenarios on multiple-server environments, a simpler and more portable way to access the target EJB application from an SCA composite is to set up a namespace binding and use the namespace binding name in the URI attribute of the binding.ejb along with `cell/persistent/`. For example:

```
uri="cell/persistent/PriceQuote"
```

where PriceQuote is the `name` field in the namespace.

The namespace binding can be of type EJB or CORBA based on the advanced scenario.

If the target EJB application which the composite is trying to access is on same cell, but on a different server, node or cluster, configure an EJB namespace binding. You can do this from the administrative console:

1. Click **Environment** > **Naming** > **Name space bindings**.
2. Select the cell scope.
3. Click **New**.
4. On the Specify binding type page, select the **EJB** binding type.
5. On the Specify basic properties page, specify the binding identifier, name in namespace, enterprise bean location such as server cluster or single server (with node), and JNDI name as needed. Use the **Name in name space** field to construct the URI as `cell/persistent/`*`name_in_namespace`*.

If the composite is running on a Version 7.0 cell and the target EJB application is running on a Version 6.1 product, configure a CORBA namespace binding with the correct Corbaname URL of the target EJB. Example Corbaname URL syntax is:

```
"corbaname:iiop:host:port/NameServiceServerRoot#jndi_name"
```

After you configure the namespace binding, use the **Name in name space** field to construct the URI; for example, `uri="cell/persistent/PriceQuote"` where PriceQuote is the value in the **Name in name space** field of the binding.

An advantage of using a namespace binding is, even when the target EJB changes, the composite definition does not need to change. Only the namespace binding needs to change accordingly.

### SCA EJB reference binding URI patterns

Use an EJB reference binding URI pattern that is appropriate for the user setup and configuration:

- If an EJB reference binding accesses a stateless session bean on the same server, the EJB reference binding URI can be a Java Naming and Directory Interface (JNDI) name of the stateless session bean. For example:

  ```
  uri="ejb/com/app/resumebank/ResumeBankHome"
  ```

- If the EJB reference binding references another SCA service with the EJB binding on the same server, then the EJB reference binding URI can be either of the following:
  - The JNDI name of the stateless session bean. For example,

    ```
    uri="ejb/com/app/resumebank/ResumeBankHome"
    ```

  - A binding that uses the SCA reference target mechanism instead of the binding URI:

    ```
    <reference name="service1" target="component_name/service_name">
    ....
    <binding.ejb/>
    </reference>
    ```

- If the EJB reference binding is accessing a stateless session bean that is deployed in the same cell, the EJB reference binding URI can be based on the cluster/node/server setup. See the following examples:
  - Accessing a stateless session bean deployed in the same cell and on cluster2

    `uri="cell/clusters/cluster2/ejb/com/app/resumebank/ResumeBankHome"`
  - Accessing a stateless session bean deployed in the same cell but on a different node.

    `uri="cell/nodes/node_name/servers/server_name/ejb/com/app/resumebank/ResumeBankHome"`
- If an EJB reference binding accesses a stateless session bean on a cell other than the current cell or on a mixed cell, then you can configure a reference binding URI in either of the following ways:
  - Create a namespace binding of either a Corba or EJB type using the administrative console. After configuring the namespace binding, use the **Name in name space** value to construct the URI as:

    `uri="cell/persistent/`*`name_in_namespace_binding`*`"`

    For example, if `neworder` is the name in the namespace binding, then the URI is `uri="cell/persistent/neworder"`.
  - Use corbaname for the EJB reference binding URI. For example:

    `corbaname:iiop:<`*`hostName`*`><`*`port`*`>/NameServiceServerRoot#`*`jndi_name`*

    where *hostName* and *port* are the respective host and port, and where the target stateless session bean is running. *jndi_name* is the JNDI name of the EJB which differs between EJB2 and EJB3.

# Configuring the SCA JMS binding

You can configure the Service Component Architecture (SCA) Java Message Service (JMS) binding for services and references to support messaging between SCA applications and JMS providers.

## Before you begin

Use the administrative console to enable the SIB service and **Configuration reload enabled** option on the application server where the application runs. Restart the server to enable the dynamic reloading of the SIB configuration files for this server. See the SIB service settings information to learn more about enabling the SIB service.

When you use the JMS binding, it is important that you follow best practice guidelines on design, configuration, and tuning of the messaging topology. Following these guidelines is especially important when you design systems for high throughput or high availability. Read the documentation on using JMS bindings in this information center, specifically "Multiple-server bus with clustering." The developerWorks articles "Configuring and tuning WebSphere MQ for performance on Windows and UNIX" and "Performance tuning for Java Messaging Service on WebSphere Application Server on z/OS" also provide useful information.

## About this task

Bindings determine how a component communicates with the world outside its domain. SCA services use bindings to describe the access mechanism that clients must use to call the service. SCA references use bindings to describe the access mechanism used to call a service.

Using the SCA JMS binding, you can make SCA components available over JMS or you can use existing JMS applications within an SCA environment. You can use the SCA JMS binding element, `<binding.jms>`, within either a component service or a component reference definition. When a JMS binding is applied within a component service interface definition, the JMS binding enables clients to access an SCA service that is offered by a JMS provider. When the JMS binding is applied on a component reference, the SCA component can consume an external JMS application or another SCA component using JMS.

WebSphere Application Server supports asynchronous messaging using JMS. The default messaging provider enables enterprise applications deployed on WebSphere Application Server to perform

asynchronous messaging without the need for you to install a JMS provider. The default messaging provider is installed and runs as part of WebSphere Application Server. The product supports the default messaging provider or WebSphere MQ as the messaging engine.

The SCA JMS Binding specification describes the <binding.jms> binding element and available attributes and options. To learn more about the <binding.jms> binding element, see the SCA JMS Binding specification documentation.

SCA with JMS supports the following messaging exchange patterns:

- request-response messaging
- one-way messaging
- one-way messaging with callback

A *request* is a message that is sent to an SCA service or sent by an SCA reference. A *response* is a message that is received back at a reference or a message that is sent by a service in response to a previous request message. In SCA, a response is always a reply to a previous request. In a one-way message, a request message is sent and a response is not expected.

This task describes the steps necessary to enable SCA applications for JMS using request-response or one-way messaging.

## Procedure

1. Identify the SCA business-level application that you want to enable for JMS messaging.
2. Identify and configure the JMS resources for your SCA application.

   You can configure JMS resources for the default messaging provider before deployment of the SCA application. During deployment of the SCA application, the product dynamically creates any JMS resources that the JMS binding needs that do not exist.

   SCA applications are bound to JMS resources through their binding definitions in a corresponding composite definition file. The composite definition file for JMS uses Java Naming and Directory Interface (JNDI) names to identify JMS administered objects that are used by the SCA runtime environment on behalf of the SCA application to provide access over the specified binding.

   You can configure the following JMS resource references in the JNDI directory or choose for the product to dynamically create the resources for you:

   - a service integration bus
   - a request queue and a response queue. A response queue is only required for request-response messaging. The physical queues and the logical queues must be defined.
   - an activation specification to handle the request to the service
   - a connection factory to process the response

   To learn more about manually creating JMS resources, see the documentation on JMS resources for the default messaging provider. To learn more about dynamically creating JMS resources, see the dynamic JMS resource creation during deployment information.
3. Configure an SCA service with the SCA JMS binding.

   To expose an SCA service over the JMS binding, add the <binding.jms> element within the service definition.

   Within the <binding.jms> element, define the following:

   - an <activationSpec> element to identify the activation specification that the binding uses to connect to a JMS destination to process request messages
   - a response <connectionFactory> element for request-response messaging patterns
   - a response <destination> element that describes the JMS destination for responses from the JMS binding. Specifying the response destination is optional because the runtime environment obtains the JMSReplyTo destination that is set on the incoming request message to determine the response

destination. If the JMSReplyTo attribute is not set on the request message, the response <destination> element is used to identify the response destination. This element is not applicable for one-way messaging patterns.

4. Configure an SCA reference with the SCA JMS binding.

   To consume or expose a JMS application or SCA reference with the JMS binding, add the <binding.jms> element within the SCA reference definition.

   Within the <binding.jms> element, define the following:

   - a <connectionFactory> element to identify the JNDI name of the connection factory used to process messages sent from the reference to the referenced service
   - a <destination> element to identify the JMS queue or topic that is used to send messages to the referenced service
   - a response <destination> element that describes the JMS destination queue used to process responses from the JMS binding. This element is optional for request-response messaging and not applicable for one-way messaging

5. Optional: Configure JMS message correlation.

   You can optionally configure a JMS correlation identification for a request message and its response. Because of the asynchronous nature of JMS, it is important to determine if message correlation is required. A request-response messaging pattern is not equivalent to synchronous messaging.

   You can use the @correlationScheme element to identify the correlation scheme used when sending a reply or callback messages. The valid values for this element are: RequestMsgIDToCorrelID, RequestCorrelIDToCorrelID, and none. The default value is RequestMsgIDToCorrelID.

   To configure JMS message correlation, you can specify a correlationID element within the composite definition file that is used within the JMS header to link two messages.

6. Optional: Invoke an operation using JMS operation selection

   - Use the default JMS binding operation selection.
   - Use JMS user property operation selection.
   - Use a JMS custom operation selector.

   Using the @nativeOperation attribute in a composite definition, your application can override operation selection; for example:

```
<service>
  <binding.jms>
  ...
    <operationProperties
      name="operationToInvoke"
      nativeOperation="selectedOperation"/>
  ...
  </binding.jms>
</service>
```

   In this example, when the configured operation selector selects the operation named *selectedOperation*, the run time invokes operation *operationToInvoke* on the target service implementation. The overriding occurs whether the service binding is configured using default JMS operation selection, JMS user property operation selection, or a JMS custom selector.

## Results

You have defined the JMS resources you need for your SCA application, configured the SCA JMS binding for your SCA services and references, and deployed your application. Your application is now ready for use.

## Example

The following example illustrates two SCA component implementations and the use of request-response and one-way messaging.

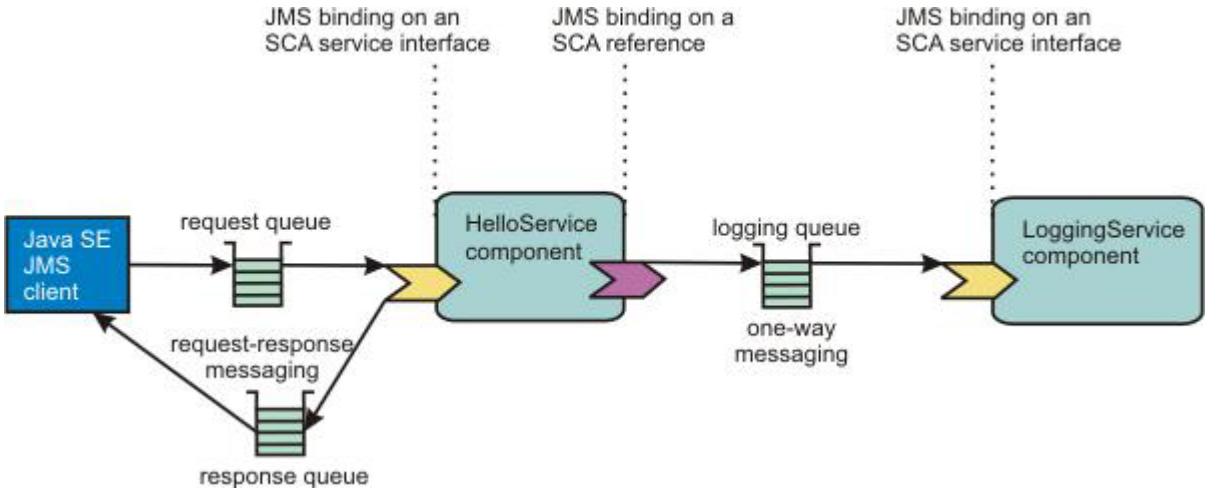

*Figure 2. SCA JMS binding example*

The HelloService component implementation illustrates the request-response message pattern. This HelloService component exposes the service interface with the name, `getGreeting`, that is used to illustrate a return response of `hello` plus the value of `getGreeting`.

The LoggingService component implementation is a logging service. This component exposes a one-way service interface with the name, `log`, that receives a message and logs the message in a repository.

The HelloService has an SCA reference to the LoggingService. Each time the HelloService service receives a message, it calls the LoggingService service to log the message.

In this example, a Thin Client for JMS application sends a message, formatted as a JMS `ObjectMessage` message type to the SCA HelloService using the `jms/SCA_sample_Request` queue. The ObjectMessage sets the `scaOperationName` property to the value, `getGreetings`. The HelloServiceComponent receives the message over the JMS HelloService binding. The HelloServiceComponent then sends a request to the referenced service, LoggingService, and the one-way operation is complete. HelloServiceComponent sends a response of `hello` plus the value of `getGreetings` to the client application using the `jms/SCA_sample_Response` queue to complete the request-response operation.

### Configuring an SCA JMS binding for a request-response service from a JMS client to SCA service

The following example describes a `<binding.jms>` element within the component definition file for a request-response message exchange pattern from a JMS client to an SCA service:

```
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
  targetNamespace="http://www.ibm.com/soa/sca/samples"
   xmlns:hw="http://www.ibm.com/soa/sca/samples"
  xmlns:ts="http://tuscany.apache.org/xmlns/sca/1.0"
   name="HelloServiceComposite">

  <component name="HelloServiceComponent">
    <implementation.java class="soa.sca.samples.jms.HelloServiceImpl"/>
    <service name="HelloService">
       <interface.java interface="soa.sca.samples.jms.HelloService"/>
         <binding.jms>
           <destination name="jms/SCA_sample_Request" type="queue"/>
           <activationSpec name="jms/SCA_sample_AS"/>
           <response>
              <destination name="jms/SCA_sample_Response" type="queue"/>
              <connectionFactory name="jms/SCA_sample_CF"/>
           </response>
           <ts:wireFormat.jmsObject/>
        </binding.jms>
    </service>

  </component>

</composite>
```

- The <destination> describes the JMS destination. The destination type is either a queue or topic. This example illustrates the JMS destination queue type. The destination is used to process requests by the JMS binding to the component implementation that contains the service interface
- The <activationSpec> element identifies the activation specification that the binding uses to connect to a JMS destination to process request messages. The activation specification name must be a JNDI name. The <activationSpec> element is only supported within the SCA <service> tag.
- The <response> element defines the resources used for processing response messages. In this example, the response element specifies the resources for sending messages from the <service> back to the client.
- The response <destination> element describes the JMS destination queue that is used to process responses from the service interface.
- The response <connectionFactory> element identifies the JNDI name of the connection factory that the binding uses to process response messages.
- The <ts:wireFormat.jmsObject/> specifies to the JMS binding that the payload of the message is of the type, javax.jms.Message (ObjectMessage).

The following example describes a <binding.jms> element within the component definition file for a one-way interaction from one SCA service to another SCA service. The <binding.jms> binding definition is similar to the HelloService; however, because the message operation is one-way, there is not a response definition.

```
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
  targetNamespace="http://www.ibm.com/soa/sca/samples"
  xmlns:hw="http://www.ibm.com/soa/sca/samples"
  xmlns:ts="http://tuscany.apache.org/xmlns/sca/1.0"
  name="HelloServiceComposite">

 <component name="LoggingService">
  <implementation.java class="soa.sca.samples.jms.LoggingServiceImpl"/>

  <service name="LoggingService">
   <interface.java interface="soa.sca.samples.jms.LoggingService"/>
         <binding.jms>
           <destination name="jms/SCA_Logging_Request" type="queue"/>
           <activationSpec name="jms/SCA_sample_AS"/>
           <ts:wireFormat.jmsObject/>
         </binding.jms>
  </service>

 </component>
</composite>
```

### Configuring an SCA JMS binding for two-way service from a JMS client to SCA reference

The following example describes a <binding.jms> element within the component definition file for a request-response message exchange pattern from a JMS client to an SCA reference:

SCA reference

```
<reference name="helloWorldService">
     <interface.java interface="my.HelloWorldService"/>
        <binding.jms>
            <connectionFactory name="jms/helloWorldServiceCF"/>
            <destination name="jms/HelloWorldService"/>
            <response>
                <destination name="jms/SCA_sample_Response"/>
            </response>
         </binding.jms>
     </reference>
```

- The <connectionFactory> element is used in the SCA reference to identify the JNDI name of the connection factory used to process messages sent from the reference to the referenced service. The <activationSpec> element is not supported in a reference.
- The <destination> element is the JMS queue or topic that is used to send messages to the referenced component implementation.
- The response <destination> element is the JMS resource that is used to receive response messages to the SCA reference.

## What to do next

Based on your business needs, you can configure an SCA JMS binding wire format or configure transactions for the SCA JMS binding.

Explore the JMS binding samples to better understand how to invoke an SCA component service using a JMS client. For information on JMS samples, see "SCA samples." To download JMS binding samples from a product website:

1. Go to the **Samples, Version 8.0** information center.
2. On the **Downloads** tab, click **FTP** or **HTTP** in the **Service Component Architecture** section.
3. In the authentication window, click **OK**.
4. From the **SCA.zip** compressed file, download the `SCA/JMS` directory and follow instructions in `SCA/JMS/documentation/readme.html` to build the files.

   Instead of building deployable files, you can use the prebuilt `jms-callback-service.jar`, `jms-twoway-oneway-service.jar`, and `jms-twoway-service.jar` files in the `SCA/installableApps` directory of the compressed file.

After you obtain your SCA components, deploy the components in an application and test the JMS binding.

## Configuring SCA JMS binding wire formats

You can configure the messaging data formats between an SCA application and a JMS producer or consumer, by configuring your SCA application to take advantage of a supported message type and data format.

### Before you begin

Configure the JMS binding for your SCA application.

### About this task

JMS producers and consumers use a variety of message types to hold application data payloads. You can use the JMS BytesMessage, ObjectMessage, or TextMessage message types. In some cases, the TextMessage message type might be expected to contain additional structure such as application data in serialized XML format.

*Wire format* describes the format of the data that is on the wire. For the SCA JMS binding, the wire format is the format of the data in the JMS message that flows through the JMS provider. Because of the variety of message types and formats, SCA services and references that are configured with a JMS binding might require additional configuration so that the runtime environment can perform the marshalling and unmarshalling required to translate between application data formats and the format of the JMS message on the wire. The additional configuration of message types is the specification of the wire format for message handling.

Whether you are configuring an SCA service or reference, it is important to recognize if the wire format is previously established by your existing messaging application infrastructure, or if you are selecting the wire format along with your SCA application. If you are starting with an application with a preexisting messaging infrastructure and you are adding your SCA application to this environment, the wire format is likely already determined by the messaging infrastructure. If you are starting with an SCA application and you intend for this application to interact with future JMS message producers or consumers, you can specify the wire format within your SCA application.

For the cases when the wire format is predetermined, it is expected behavior that the wire format enables a natural mapping to the format expected by your preexisting message producers and consumer when dealing with input and non-exception output. However, exception conditions might not be handled

according to the convention for the wire format type in your existing messaging application infrastructure. If you want exceptions to flow over the JMS binding, you might need to adjust the producers or consumers interacting with your SCA application over the JMS binding according to the exception handling behavior.

## Procedure

1. Determine if you are using a wire format that is predetermined by your existing messaging infrastructure or if you are starting with an SCA application and defining the message wire format.
2. Determine the message type to use for your wire format.

   See Supported message types for SCA JMS binding wire formats.
3. If you are using a wire format predetermined by your existing messaging infrastructure, add the corresponding wire format element into the composition definition file.
4. Ensure that your SCA service and service client implementation and interfaces map appropriately for the specific wire format that you selected.
5. (optional) If you want exception checking to occur over the JMS binding, ensure that the JMS producer and consumer that is interoperating with your SCA application follows the SCA JMS binding exception handling procedures described previously.
6. If you are starting with an SCA application and defining the message infrastructure, add the appropriate wire format element into the composition definition file, and ensure that your future JMS producer or consumer applications understand how to interoperate with this message data format.

## Results

You have configured the a messaging data format between an SCA application and a JMS producer or consumer.

## Examples of configuring SCA JMS binding wire formats

The following examples illustrate the configuration of composite definition files using the various wire format schemes. Component references are configured in an analogous manner

### TextMessage with serialized XML wire format that maps data using JAXB

This example illustrates the TextMessage with serialized XML wire format that maps data using JAXB, which is the default wire format:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
    targetNamespace="http://test/soa/sca/"
    xmlns:ts="http://tuscany.apache.org/xmlns/sca/1.0"
    name="JBC">

      <component name="JAXBComponent">
        <implementation.java class="test.backend.HelloWorldJAXBBackendImpl" />
        <service name="HelloWorldJAXBService">
          <interface.wsdl interface="http://test.hello#wsdl.interface(HelloWorld)"/>
          <binding.jms>
            <destination name="jms/Request1" type="queue" create="never"/>
            <activationSpec name="jms/AS1"/>
            <response>
              <destination name="jms/Response1" type="queue" create="never"/>
              <connectionFactory name="jms/CF" create="never"/>
            </response>
           <!-- No wire format element is necessary, the default is used. -->
         </binding.jms>
      </service>
    </component>
```

### ObjectMessage wire format that maps to the `java.lang.Object` class

This example illustrates the ObjectMessage wire format that maps to the `java.lang.Object` class:

```
<component name="SerializableComponent">
    <implementation.java class="test.backend.HelloWorldSerializableBackendImpl"/>
    <service name="HelloWorldSerializableService">
        <interface.java interface="test.HelloWorldSerializableService"/>
        <binding.jms>
          <destination name="jms/Request2" type="queue" create="never"/>
          <activationSpec name="jms/AS2"/>
          <response>
            <destination name="jms/Response2"/>
            <connectionFactory name="jms/CF" create="never"/>
          </response>
          <!-- The wire format element must appear last in the binding definition
               to conform to the schema. -->
          <ts:wireFormat.jmsObject/>
        </binding.jms>
    </service>
</component>
```

### TextMessage wire format that maps to single string messages

This example illustrates the TextMessage wire format that maps to single string messages:

```
<component name="JMSTextBackendComponent">
    <implementation.java class="test.backend.HelloWorldTextBackendImpl" />
    <service name="HelloWorldTextService">
       <interface.java interface="test.HelloWorldTextService"/>
       <binding.jms>
          <destination name="jms/Request3"/>
          <activationSpec name="jms/AS3"/>
          <response>
             <destination name="jms/Response3"/>
             <connectionFactory name="jms/CF" create="never"/>
          </response>
          <!-- The wire format element must appear last in the binding definition
               to conform to the schema. -->
          <ts:wireFormat.jmsText/>
      </binding.jms>
    </service>
</component>
```

### BytesMessage wire format that maps to single byte array messages

This example illustrates the BytesMessage wire format that maps to single byte array messages:

```
<component name="JMSBytesBackendComponent">
    <implementation.java class="test.backend.HelloWorldBytesBackendImpl" />
    <service name="HelloWorldBytesService">
      <interface.java interface="test.HelloWorldBytesService"/>
      <binding.jms>
        <destination name="jms/Request4"/>
        <activationSpec name="jms/AS4"/>
        <response>
          <destination name="jms/Response4"/>
          <connectionFactory name="jms/CF" create="never"/>
        </response>
        <!-- The wire format element must appear last in the binding definition
             to conform to the schema. -->
        <ts:wireFormat.jmsBytes/>
      </binding.jms>
    </service>
</component>
```

### JMS message wire format that does not extract the message payload and maps to the `javax.jms.Message` class

This example illustrates the JMS Message wire format that does not extract the message payload and maps to the `javax.jms.Message` class:

```
<component name="JMSTextBackendComponent">
    <implementation.java class="test.backend.HelloWorldTextBackendImpl" />
    <service name="HelloWorldTextService">
      <interface.java interface="test.HelloWorldTextService"/>
      <binding.jms>
        <destination name="jms/Request4"/>
        <activationSpec name="jms/AS4"/>
        <response>
          <destination name="jms/Response4"/>
          <connectionFactory name="jms/CF" create="never"/>
        </response>
        <!-- The wire format element must appear last in the binding definition
             to conform to the schema. -->
        <ts:wireFormat.jmsText/>
      </binding.jms>
    </service>
</component>
```

### Examples of TextMessage messages using JAXB

The following examples illustrate the contents of TextMessage messages produced by using JAXB marshalling in the default wire format. These examples are based on using the bottom-up approach of developing SCA applications starting with a Java interface, rather than the best practice of starting with a WSDL interface, such that the runtime environment generates the WSDL file.

- For a client invoking an SCA reference with the following interface method:

  ```
  package com.ibm.test.soa.sca;
  public String getGreetings(String name);
  ```

  The binding produces a TextMessage request message with XML payload similar to the following:

  ```
  <ns2:getGreetings xmlns:ns2="http://sca.soa.test.ibm.com/">
     <arg0>Mike</arg0>
  </ns2:getGreetings>
  ```

  The response message must be a TextMessage with XML payload similar to the following:

  ```
  <ns2:getGreetingsResponse xmlns:ns2="http://sca.soa.test.ibm.com/">
     <return>Hello Mike</return>
  </ns2:getGreetingsResponse>
  ```

  Similarly, an SCA service bound to a destination, from which TextMessage messages of this format were delivered, requires the same service interface method; for example:

  ```
  package com.ibm.test.soa.sca;
  public String getGreetings(String name);
  ```

- For a client invoking an SCA reference with the following interface method:

  ```
  package com.ibm.test.soa.sca;
  public void getGreeting(FullName name, String string);
  ```

  In this example, the `FullName` type is mapped to Java using JAXB using the following schema definition:

  ```
  <schema targetNamespace="http://www.ibm.com/test/soa/sca/"
      elementFormDefault="qualified"
      xmlns=http://www.w3.org/2001/XMLSchema>

      <complexType name="FullName">
        <sequence>
          <element name="firstName" type="string"/>
          <element name="lastName" type="string"/>
        </sequence>
      </complexType>
  </schema>
  ```

  The binding produces a TextMessage request message with XML payload similar to the following:

  ```
  <ns2:getGreetings xmlns:ns2="http://sca.soa.test.ibm.com/">
     <arg0>Mike</arg0>
  </ns2:getGreetings>
  ```

The response message must be a TextMessage request message with XML payload similar to the following:

```
<ns3:getGreeting xmlns:ns3="http://sca.soa.test.ibm.com/"
   xmlns:ns2="http://www.ibm.com/test/soa/sca/">
   <arg0>
        <ns2:firstName>Bob</ns2:firstName>
        <ns2:lastName>Jones</ns2:lastName>
   </arg0>
   <arg1>home</arg1>
</ns3:getGreeting>
```

Similarly, an SCA service bound to a destination, from which TextMessage messages of this format were delivered, requires the same service interface method; for example:

```
package com.ibm.test.soa.sca;
public String getGreeting(FullName name, String string);
```

***Supported message types for SCA JMS binding wire formats:***

For a Service Component Architecture (SCA) application that has a Java Message Service (JMS) binding to send and receive messages, the application must use a message type and data format that the JMS binding supports. Supported message types include JMS BytesMessage, ObjectMessage, and TextMessage. The message type to use depends on whether you are configuring an SCA service or reference and whether the JMS wire format of the service or reference is already determined.

The following sections describe supported message types:

- Message types for SCA services when the JMS binding wire format is predetermined
- Message types for SCA references when the JMS binding wire format is predetermined
- Message types for SCA services and references when the JMS binding wire format is not predetermined

**Message types for SCA services when the JMS binding wire format is predetermined**

For an SCA service to consume messages that are produced in a predetermined JMS binding wire format, use the following message types:

- **TextMessage or BytesMessage with serialized XML wire format that maps data using JAXB**

  The TextMessage or BytesMessage wire format uses Java Architecture for XML Binding (JAXB) technology to marshal and unmarshal data into XML. This wire format is the default wire format. Thus, this wire format applies if no wire format element is specified in the composite definition file. To specify this wire format, add the following wire format element to the composite definition file:

  ```
  {http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsdefault
  ```

  – **Mapping a request message payload to input arguments**

    The TextMessage or BytesMessage payload contains XML data that represents serialized input arguments. The format of the service is described by a WSDL interface that is specified by either a `interface.wsdl` element from the component service definition, or by a WSDL that is generated by the Java interface of the SCA service if the `interface.wsdl` element is not explicitly defined.

    This runtime environment Java-to-WSDL mapping is based on the JAXB and JAX-WS specifications. The default behavior results in a document-literal wrapped WSDL interface, except when there is a single parameter method. A single argument input parameter is **not** wrapped by a "wrapper" element corresponding to the operation name.

    JAXB unmarshalling is used to deserialize incoming XML payloads into the service arguments that are passed to the component implementation.

  – **Mapping an output return value to a response message payload**

    The return value of the service method is marshalled in a similar manner to the unmarshalling of the request message input. The marshalling uses JAXB and JAX-WS technology to map to XML in a WSDL defined format such that the WSDL is specified explicitly or the runtime environment

generates the WSDL from the Java interface. The resulting serialized XML is never wrapped by the operation name, even if the WSDL defines a wrapper element.

If the request payload is a BytesMessage, the non-wrapped XML is set as the payload of a response BytesMessage. If the request payload received is a TextMessage, the non-wrapped XML is set as a TextMessage. The response format is always the same as the request message format.

– **Mapping exceptions to a response message payload**

If you have a checked exception, the runtime environment will not marshall the exception. Instead, the runtime environment serializes the fault, as defined by JAX-WS, into an XML payload of a response TextMessage. If you have an unchecked exception, an instance of `RuntimeException` is set as the payload of a response ObjectMessage. In both cases, a Boolean message property with the name, `org_apache_tuscany_sca_fault`, is set to`true` on the response message. To learn more about exceptions and faults, see the documentation on using business exceptions with SCA interfaces.

- **TextMessage with serialized XML wire format that maps data using JAXB**

The TextMessage wire format uses JAXB technology to marshal and unmarshal data into XML. To specify this wire format, add the following wire format element to the composite definition file:

```
{http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsTextXML
```

– **Mapping a request message payload to input arguments**

The TextMessage payload contains XML data that represents serialized input arguments. The format of the service is described by a Web Services Description Language (WSDL) interface that is specified by either a `interface.wsdl` element from the component service definition, or by a WSDL that is generated by the Java interface of the SCA service if the `interface.wsdl` element is not explicitly defined. This runtime environment Java-to-WSDL mapping is based on the JAXB and Java API for XML-Based Web Services (JAX-WS) specifications. This mapping results in a document-literal wrapped WSDL interface; however, the presence of the operation-level wrapper does not impact operation selection for the messages. JAXB unmarshalling is used to deserialize incoming XML payloads into the service arguments that are passed to the component implementation.

– **Mapping an output return value to a response message payload**

The return value of the service method is marshalled in a similar manner to the unmarshalling of the request message input. The marshalling uses JAXB and JAX-WS technology to map to XML in a WSDL defined format such that the WSDL is specified explicitly or the runtime environment generates the WSDL from the Java interface. The resulting serialized XML is the payload of a TextMessage response message.

– **Mapping exceptions to a response message payload**

If you have a checked exception, the runtime environment will not marshall the exception. Instead, the runtime environment serializes the fault, as defined by JAX-WS, into an XML payload of a response TextMessage. If you have an unchecked exception, an instance of `RuntimeException` is set as the payload of a response ObjectMessage. In both cases, a Boolean message property with the name, `org_apache_tuscany_sca_fault`, is set to`true` on the response message. To learn more about exceptions and faults, see the documentation on using business exceptions with SCA interfaces.

- **ObjectMessage wire format that maps to the `java.lang.Object` class**

The ObjectMessage wire format uses serialized Java objects. To specify this wire format, add the following wire format element to the composition definition file:

```
{http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsObject
```

– **Mapping a request message payload to input arguments**

The ObjectMessage payload returned by a `getObject()` method is typically an array that maps to the input parameters of your service method. In the case of a single non-array object, the object is mapped to the single argument of a method with only one parameter. The parameter type must be serializable by Java and implement the Java serialization interface, `java.io.Serializable`.

For a method with exactly one parameter, the payload returned from `getObject()` can either be unwrapped, as described in the previous special case, or wrapped in an array of size one that maps to the single input parameter. When the runtime cannot determine if the payload array is a wrapper

array that maps to the input parameters of your service method or if the payload array is the actual argument itself, the default behavior is to map the payload directly to the single argument of the method. You can override this behavior by setting the `wrapSingle` attribute on the `wireFormat.jmsObject` element to `true`. When `wrapSingle` is set to `true`, the content of the payload array, which is a single element because the size of the array is one, is mapped to the single argument of the method. The payload array itself is not mapped to the method argument.

  - **Mapping an output return value to a response message payload**

    The return value of the service method is set as the ObjectMessage payload. The return type must also be Java-serializable and implement the Java serialization interface, `java.io.Serializable`. In the case of a void return type, the response payload is set to the value, `null`.

  - **Mapping exceptions to a response message payload**

    If you have a checked exception, the runtime environment sets the exception as the ObjectMessage payload. For an unchecked exception, an instance of `RuntimeException` is set as the payload of a response ObjectMessage. In both cases, a Boolean message property with name `org_apache_tuscany_sca_fault` is set to `true` on the response message.

- **TextMessage wire format that maps to single `String` messages**

  Use the `wireFormat.jmsText` format to map between the payload of a TextMessage and a single `String` argument or return value. To specify this wire format, add the following wire format element to the composition definition file:

  ```
  {http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsText
  ```

  - **Mapping a request message payload to input arguments**

    When using this wire format, the service interface method must contain a single parameter of type `String`; for example: `void myMethod(String str)`. The TextMessage payload that is returned by the `getText()` method is mapped to this single parameter.

  - **Mapping an output return value to a response message payload**

    The return type of the service method is typically either `String` or `void`. If the return type is `String`, the return value is set as the response TextMessage payload. If the return type is `void`, a `null` value is set as the payload. For a return value of type other than `String`, the payload is defined by setting a `String.valueOf()` on the return value.

  - **Mapping exceptions to a response message payload**

    Rather than defining a convention for mapping exceptions to a TextMessage, ObjectMessage messages are used to map exceptions. If you have a checked exception, the runtime environment sets the exception as the ObjectMessage payload. For an unchecked exception, an instance of `RuntimeException` is set as the payload of a response ObjectMessage message. In both cases, a Boolean message property with name `org_apache_tuscany_sca_fault` is set to `true` on the response message.

- **BytesMessage with XML wire format that maps data using JAXB**

  The BytesMessage wire format uses JAXB technology to marshal and unmarshal data into XML. To specify this wire format, add the following wire format element to the composite definition file:

  ```
  {http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsBytesXML
  ```

  - **Mapping a request message payload to input arguments**

    The input arguments are marshalled into an XML payload, and added to a request BytesMessage. The format of the service is described by a WSDL interface that is specified by either a `interface.wsdl` element from the component service definition, or by a WSDL that is generated by the Java interface of the SCA service if the `interface.wsdl` element is not explicitly defined. This runtime environment Java-to-WSDL mapping is based on the JAXB and JAX-WS specifications. This mapping results in a document-literal wrapped WSDL interface; however, the presence of the operation-level wrapper does not impact operation selection for the messages. The product uses JAXB marshalling to serialize the Java client input argument into the XML payload.

  - **Mapping exceptions to a response message payload**

The runtime environment first determines whether the response message represents an unchecked exception condition by looking for the `org_apache_tuscany_sca_fault` Boolean message property. If this property is set to `true` on the response message, the runtime environment expects an ObjectMessage as the response. When this condition occurs, a ServiceRuntimeException error is returned to the client. If this property is not set, or set to `false`, the message is a BytesMessage that can represent either a checked exception or normal output data. If a checked exception, the BytesMessage payload contains a fault in XML serialized form. The runtime environment deserializes the fault using JAXB unmarshalling, and returns the corresponding checked exception back to the client, wrappering the fault data. For more information about exceptions and faults, see the topic on using business exceptions with SCA interfaces.

– **Mapping an output return value to a response message payload**

The return value of the service method is marshalled in a similar manner to the unmarshalling of the request message input. The marshalling uses JAXB and JAX-WS technology to map to XML in a WSDL defined format such that the WSDL is specified explicitly or the runtime environment generates the WSDL from the Java interface. The resulting XML of the response BytesMessage is deserialized using JAXB unmarshalling and returned to the client.

- **BytesMessage wire format that maps to single byte array messages**

Use the `wireFormat.jmsBytes` format to map between the payload of a BytesMessage and a `byte[]` argument or return value. To specify this wire format, add the following wire format element to the composition definition file:

```
{http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsBytes
```

– **Mapping a request message payload to input arguments**

When using this wire format, the service interface method must contain a single parameter of type `byte[]`; for example: `void myMethod(byte[] bytes);`. The BytesMessage payload that is obtained using the `readBytes()` method is mapped to this single parameter.

– **Mapping an output return value to a response message payload**

The return type of the service method must be `byte[]` or `void`. If the return type is `byte[]`, the return value is set as the response BytesMessage payload.

– **Mapping exceptions to a response message payload**

When using this wire format, ObjectMessage messages are used to map exceptions, as in the ObjectMessage wire format case. If you have a checked exception, the runtime environment sets the exception as the ObjectMessage payload. For an unchecked exception, an instance of `RuntimeException` is set as the payload of a response ObjectMessage message. In both cases, a Boolean message property with name `org_apache_tuscany_sca_fault` is set to `true` on the response message.

- **JMS message wire format that does not extract the message payload and maps to the `javax.jms.Message` class**

You can use a wire format mechanism that instructs the JMS binding to provide the raw JMS message to the service implementation without extracting the payload out of the message. To use this wire format, the service interface must consist of a single method with one input parameter of `javax.jms.Message`, such as:

```
void methodA(javax.jms.Message msg);
```

The method name is not important; only the input parameter type is relevant. This method is similar to the `javax.jms.MessageListener` interface. The support for this method enables existing message-driven beans logic to be reused in SCA component implementations.

Use the default wire format to enable this mechanism to obtain the raw JMS message. To specify the default wire format, add the following wire format element to the composition definition file:

```
{http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsdefault
```

Because this wire format is the default, the same result is achieved by not specifying a wire format element.

This wire format is not the same as the TextMessage JAXB XML format. In this scenario, the wire format selection does not describe a specific format of data on the wire. Instead, the specification of this wire format indicates to the runtime environment to identify this specialty case to obtain the raw JMS message and handle the incoming data by passing the raw JMS message to the application.

The response message is a TextMessage with a `null` payload. The response message is sent unless the `onMessage` method is annotated as a one-way operation.

**Message types for SCA references when the JMS binding wire format is predetermined**

For an SCA reference to produce messages that are consumed in a predetermined JMS binding wire format, use the following message types:

- **TextMessage with serialized XML wire format that maps data using JAXB**

  The TextMessage wire format uses JAXB technology to marshal and unmarshal data into XML. To specify this wire format, add the following wire format element to the composite definition file:

  ```
  {http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsTextXML
  ```

  – **Mapping input arguments to a request message payload**

    Using this wire format, the input arguments are marshalled into an XML payload, and added to a request TextMessage. The format of the service is described by a WSDL file interface that is specified by either a `interface.wsdl` element from the component service definition, or by a WSDL that is generated from the Java interface of the SCA service if the `interface.wsdl` element is not explicitly defined. The Java-to-WSDL mapping is based on the JAXB and Java API for XML-Based Web Services (JAX-WS) specifications. This mapping results in a document-literal wrapped WSDL file, and the wrapper element corresponds to the operation name. JAXB marshalling is used to serialize the Java client input arguments into the XML payload.

  – **Mapping a response message payload to output return value and exceptions**

    The runtime environment first determines whether the response message represents an unchecked exception condition by checking for the `org_apache_tuscany_sca_fault` Boolean message property. If this property is set to `true` on the response message, the runtime environment expects an ObjectMessage as the response. When this condition occurs, a ServiceRuntimeException error is returned to the client. If this property is not set, or set to `false`, the message is a TextMessage that can represent either a checked exception or output data.

    The return value of the service method is unmarshalled in a similar manner to the marshalling of the request message input. The marshalling uses JAXB and JAX-WS technology to map to XML in a WSDL defined format such that the WSDL is specified explicitly or the runtime environment generates the WSDL from the Java interface. The XML payload of the response TextMessage message is deserialized using JAXB unmarshalling and returned to the client.

    If you have a checked exception, the TextMessage payload contains a fault in XML serialized form. The runtime environment deserializes the fault using JAXB unmarshalling and the corresponding checked exception is sent back to the client, wrappering the fault data. To learn more about exceptions and faults, see the documentation on using business exceptions with SCA interfaces.

- **The BytesMessage or TextMessage with serialized XML wire format that maps data using JAXB**

  The BytesMessage or TextMessage wire format uses JAXB technology to marshal and unmarshal data into XML. This wire format is the default wire format. Thus, this wire format applies if no wire format element is specified in the composite definition file. To specify this wire format, add the following wire format element to the composite definition file:

  ```
  {http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsdefault
  ```

  – **Mapping input arguments to a request message payload**

    Using this wire format, the input arguments are marshalled into an XML payload, and added to a request BytesMessage. The format of the service is described by a WSDL file interface that is specified by either a `interface.wsdl` element from the component reference definition, or by a WSDL that is generated from the Java interface of the SCA service if an `interface.wsdl` element is not defined.

The runtime Java-to-WSDL mapping is based on the JAXB and JAX-WS specifications. This mapping results in a document-literal wrapped WSDL file, and the wrapper element corresponds to the operation name, except when there is a single parameter method. A single argument input parameter is never wrapped by a wrapper element corresponding to the operation name. JAXB marshalling is used to serialize the Java client input arguments into the XML payload.

– **Mapping a response message payload to output return value and exceptions**

The runtime environment first determines whether the response message represents an unchecked exception condition by checking for the `org_apache_tuscany_sca_fault` Boolean message property. If this property is set to `true` on the response message, the runtime environment expects an ObjectMessage as the response. When this condition occurs, a ServiceRuntimeException error is returned to the client. If this property is not set, or set to `false`, the message is a BytesMessage or TextMessage that can represent either a checked exception or output data.

If you have a checked exception, the BytesMessage or TextMessage payload contains a fault in XML serialized form. The runtime environment deserializes the fault using JAXB unmarshalling and the corresponding checked exception is sent back to the client, wrappering the fault data. To learn more about exceptions and faults, see the topic on using business exceptions with SCA interfaces.

For non-exception output data, the return value of the service method is unmarshalled in a similar manner to the marshalling of the request message input. The unmarshalling uses JAXB and JAX-WS technology to map to XML in a WSDL defined format such that the WSDL is specified explicitly or the runtime environment generates the WSDL from the Java interface. The XML payload is always expected to be in unwrapped format even if the WSDL defines a wrapper with an operation name. The XML payload of the response BytesMessage or TextMessage is deserialized using JAXB unmarshalling and returned to the client.

- **ObjectMessage wire format that maps to the `java.lang.Object` class**

The ObjectMessage wire format uses serialized Java objects. To specify this wire format, add the following wire format element to the composition definition file:

```
{http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsObject
```

– **Mapping input arguments to a request message payload**

The arguments that are passed to the SCA reference are wrapped in an array and are set into the request ObjectMessage payload using the `setObject()` method, except for methods with exactly one parameter. By default, arguments are not wrapped in an array for methods with a single argument unless the `wrapSingle` attribute is set to `true` on the `wireFormat.jmsObject` element.

– **Mapping a response message payload to output return value and exceptions**

The runtime environment obtains the response ObjectMessage payload using the `getObject()` method. If the payload object is an unchecked exception, a ServiceRuntimeException error is returned to the client. If the payload object is an instance of a checked exception, the checked exception is returned to the client If the payload object represents non-exception output data, that payload object is returned back to the client application.

- **TextMessage wire format that maps to single string messages**

Use the `wireFormat.jmsText` format to map between the payload of a TextMessage and a single `String` argument or return value. To specify this wire format, add the following wire format element to the composition definition file:

```
{http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsText
```

– **Mapping input arguments to a request message payload**

When using this wire format, the service interface method typically has a single parameter of type `String` ; for example: `void myMethod(String str)`. The single `String` passed to the SCA reference is set into the request TextMessage payload by the `setText()` method.

For method signatures with different input parameters, the result of performing a `String.valueOf()` method on the first argument is set as the payload, regardless of how many arguments are present.

– **Mapping a response message payload to output return value and exceptions**

The return type of the service method is must be either `String` or `void`; for example: `String myMethod(String str)`.

The runtime environment first determines whether the response message represents an exception condition by checking for the `org_apache_tuscany_sca_fault` Boolean message property. If this property is set to `true` on the response message, the runtime environment expects an ObjectMessage message as the response, and the message payload is obtained by the `getObject()` method. If the payload object is an unchecked exception, a ServiceRuntimeException is returned back to the client. If the payload object is an instance of a checked exception, that checked exception is returned to the client.

If this property is not set, or set to `false`, the runtime environment expects non-exception output data and a TextMessage response. In this case, if the return type is `String`, a `getText()` method used to obtain the payload object that will be returned to the client application as a `String` value.

- **The BytesMessage with XML wire format that maps data using JAXB**

  The BytesMessage wire format uses JAXB technology to marshal and unmarshal data into XML. To specify this wire format, add the following wire format element to the composite definition file:

  `{http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsBytesXML`

  – **Mapping input arguments to a request message payload**

    Using this wire format, the input arguments are marshalled into an XML payload, and added to a request BytesMessage. The format of the service is described by a WSDL file interface that is specified by either a `interface.wsdl` element from the component reference definition, or by a WSDL that is generated from the Java interface of the SCA service if an `interface.wsdl` element is not defined.

    The runtime Java-to-WSDL mapping is based on the JAXB and JAX-WS specifications. By default, this mapping results in a document-literal wrapped WSDL file, and the wrapper element corresponds to the operation name. JAXB marshalling is used to serialize the Java client input arguments into the XML payload.

  – **Mapping a response message payload to output return value and exceptions**

    The runtime environment first determines whether the response message represents an unchecked exception condition by checking for the `org_apache_tuscany_sca_fault` Boolean message property. If this property is set to `true` on the response message, the runtime environment expects an ObjectMessage as the response. When this condition occurs, a ServiceRuntimeException error is returned to the client. If this property is not set, or set to `false`, the message is a BytesMessage that can represent either a checked exception or normal output data.

    If you have a checked exception, the BytesMessage payload contains a fault in XML serialized form. The runtime environment deserializes the fault using JAXB unmarshalling and the corresponding checked exception is sent back to the client, wrappering the fault data. To learn more about exceptions and faults, see the topic on using business exceptions with SCA interfaces.

    For non-exception output data, the return value of the service method is unmarshalled in a similar manner to the marshalling of the request message input. The unmarshalling uses JAXB and JAX-WS technology to map to XML in a WSDL defined format such that the WSDL is specified explicitly or the runtime environment generates the WSDL from the Java interface. The XML payload of the response BytesMessage is deserialized using JAXB unmarshalling and returned to the client.

- **BytesMessage wire format that maps to single byte array messages**

  Use the `wireFormat.jmsBytes` format to map between the payload of a BytesMessage and a single `byte[]` argument or return value. To specify this wire format, add the following wire format element to the composition definition file:

  `{http://tuscany.apache.org/xmlns/sca/1.0}wireFormat.jmsBytes`

  – **Mapping input arguments to a request message payload**

    When using this wire format, the service interface method must contain a single parameter of type `byte[]`; for example: `void myMethod(byte[] bytes);`. The single argument is mapped to a BytesMessage payload using the `writeBytes()` method.

  – **Mapping a response message payload to output return value and exceptions**

The return type of the service method must be `byte[]` or `void`.

The runtime environment first determines whether the response message represents an exception condition by checking for the `org_apache_tuscany_sca_fault` Boolean message property. If this property is set to `true` on the response message, the runtime environment expects an ObjectMessage message as the response, and the message payload is obtained by the `getObject()` method. If the payload object is an unchecked exception, a ServiceRuntimeException error is returned to the client. If the payload object is an instance of a checked exception, that checked exception is returned to the client

If this property is not set, or set to `false`, the runtime environment expects non-exception output data and a BytesMessage response message. In this case, a `readBytes()` method is used to obtain the payload object that will be returned to the client application as a `byte[]` value.

**Message types for SCA services and references when the JMS binding wire format is not predetermined**

Suppose you are adding a JMS binding to an SCA service or reference to produce messages that will be consumed at a future time by a JMS producer or consumer, and there is not a predetermined wire format.

It is a best practice to use the default wire format when starting with the SCA application. Use the JAXB programming model with the top-down approach to developing SCA applications as these service implementations and clients are easily used with the SCA default binding, the SCA web service binding, and the SCA JMS binding. Adopting an XML-centric view of your business data provides maximum portability across diverse platforms and technologies, and takes advantage of the design goals of a typical SOA environment. To learn more about top-down development of SCA applications, see the developing SCA applications from existing WSDL files documentation.

If you have business data that is described within Java classes that implement the Java serialization interface, `java.io.Serializable`, but the JAXB marshalling and unmarshalling does not satisfactorily preserve the data over the wire, you can use the ObjectMessage wire format.

***Configuring JMS binding request and response wire formats:***

You can configure the messaging data formats between an SCA application and a JMS producer or consumer, by configuring your SCA application to take advantage of a supported message type and data format. In general, each wire format can map to the service or reference side, and even into serialization and deserialization. As a result, you can configure each service or reference request and response to use different wire formats.

**Before you begin**

Configure the JMS binding for your SCA application. Then, configure the JMS binding wire format.

**About this task**

In most cases, the response wire format can be the same as the request wire format for a messaging application. However, in certain scenarios this might not be reasonable, such as when the inputs and outputs of an operation cannot use the same wire format. In this situation, you can override the request wire format by explicitly configuring the response wire format with a `wireformat` element as a child on the `binding.jms response` element.

When choosing a request and response wire format, consider any restrictions imposed by the application itself and also the limitations of any particular wire format. For example, consider the following interface method:

```
public MyJavaObject method(MyJAXBObject mjo)
```

MyJavaObject is not an XML-serializable object and MyJAXBObject is not Java-serializable so you cannot use only one wire format. However, you can use wireFormat.jmsTextXML for the request wire format and wireFormat.jmsObject for the response.

### Procedure

1. Open an editor on a composite definition file and configure a reference-side wire format.

   A reference-side wire format resembles the following:

   ```
   <component name="JAXBJMSFrontendReqRespWFComponent">
     <implementation.java class="com.ibm.test.soa.sca.frontend.HelloWorldJAXBFrontendImpl"/>
       <reference name="hwJAXBService">
         <interface.java interface="com.ibm.test.soa.sca.HelloWorldJAXBService"/>
           <binding.jms>
             <destination name="jms/SCA_JMS_Request1"/>
             <connectionFactory name="jms/SCA_JMS_CF"/>
             <response>
               <destination name="jms/SCA_JMS_Response1"/>
               <connectionFactory name="jms/SCA_JMS_CF"/>
               <ts:wireFormat.jmsObject/>
             </response>
           </binding.jms>
       </reference>
   </component>
   ```

   In the example component configuration, the binding level wire format is the default because no wire format is specified. However, the response wire format is overridden by the jmsObject wire format.

2. Open an editor on a composite definition file and configure a service-side wire format.

   A service-side wire format resembles the following:

   ```
   <component name="JAXBJMSBackendReqRespWFComponent">
     <implementation.java class="com.ibm.test.soa.sca.backend.HelloWorldJAXBBackendImpl"/>
       <service name="HelloWorldJAXBService">
         <interface.java interface="com.ibm.test.soa.sca.HelloWorldJAXBService"/>
           <binding.jms>
             <destination name="jms/SCA_JMS_Response1"/>
             <activationSpec name="jms/SCA_JMS_AS1"/>
             <response>
               <destination name="jms/SCA_JMS_Response1"/>
               <connectionFactory name="jms/SCA_JMS_CF"/>
               <ts:wireFormat.jmsObject/>
             </response>
           </binding.jms>
       </service>
   </component>
   ```

   The response wire format is always the same as the request wire format unless the response level wire format is explicitly configured.

### Results

You have configured the request and response wire format for a messaging application.

### Examples

More example component configurations that show request and response wire formats follow.

#### Component configuration for a multiple-parameter reference

```
<component name="MultipleParameterFrontendReqRespWFComponent">
  <implementation.java class="com.ibm.test.soa.sca.frontend.MultipleParameterFrontendImpl"/>
    <reference name="mpService">
      <interface.java interface="com.ibm.test.soa.sca.MultipleParameterService"/>
        <binding.jms>
          <destination name="jms/SCA_JMS_Request2"/>
          <connectionFactory name="jms/SCA_JMS_CF"/>
          <response>
            <destination name="jms/SCA_JMS_Response2"/>
            <connectionFactory name="jms/SCA_JMS_CF"/>
```

```
          <ts:wireFormat.jmsObject/>
        </response>
        <ts:wireFormat.jmsObject/>
      </binding.jms>
    </reference>
</component>
```

### Component configuration for a multiple-parameter service that uses jmsBytesXML wire format

```
<component name="MultiParameterJMSBackendReqRespWFComponent">
  <implementation.java class="com.ibm.test.soa.sca.backend.MultipleParameterBackendImpl"/>
    <service name="MultipleParameterService">
      <interface.java interface="com.ibm.test.soa.sca.MultipleParameterService"/>
        <binding.jms>
          <destination name="jms/SCA_JMS_Request2"/>
          <activationSpec name="jms/SCA_JMS_AS2"/>
          <response>
            <destination name="jms/SCA_JMS_Response2"/>
            <connectionFactory name="jms/SCA_JMS_CF" create="never"/>
            <ts:wireFormat.jmsBytesXML//>
          </response>
        </binding.jms>
    </reference>
</component>
```

### Component configuration for a reference that uses jmsText wire format for the response and a jmsCustom format for the binding

```
<component name="FrontEndWireFormatHandlerReqRespWFComponent">
  <implementation.java class="com.ibm.test.soa.sca.frontend.CustomReqRespFrontEndComponent"/>
    <reference name="frontEnd">
        <binding.jms>
          <destination name="jms/SCA_JMS_Request3"/>
          <connectionFactory name="jms/SCA_JMS_CF"/>
          <response>
            <destination name="jms/SCA_JMS_Response3"/>
            <connectionFactory name="jms/SCA_JMS_CF"/>
            <ts:wireFormat.jmsText//>
          </response>
          <ts:wireFormat.jmsCustom class="com.ibm.test.soa.sca.frontend.custom.FrontEndReqRespWireFormatHandler"/>
        </binding.jms>
    </reference>
</component>
```

### Component configuration for a service that uses jmsText wire format for the response and a jmsCustom format for the binding

```
<component name="BackEndWireFormatHandlerReqRespWFComponent">
  <implementation.java class="com.ibm.test.soa.sca.backend.CustomReqRespBackEndComponent"/>
    <service name="CustomReqResp">
        <binding.jms>
          <destination name="jms/SCA_JMS_Request3" type="queue" create="never"/>
          <activationSpec name="jms/SCA_JMS_AS3"/>
          <response>
            <destination name="jms/SCA_JMS_Response3"/>
            <connectionFactory name="jms/SCA_JMS_CF" create="never"/>
            <ts:wireFormat.jmsText//>
          </response>
          <ts:wireFormat.jmsCustom class="com.ibm.test.soa.sca.backend.custom.BackendReqRespDBH"/>
        </binding.jms>
    </service>
</component>
```

### What to do next

Deploy and test the wire format configuration in your SCA application.

## Configuring transactions for the SCA JMS binding

You can configure the Service Component Architecture (SCA) Java Message Service (JMS) binding for services and references to take advantage of transaction quality of service behaviors.

### About this task

SCA provides declarative mechanisms in the form of intents for describing the transactional environment required by components.

The SCA JMS binding supports transacting message delivery with the global transaction of a component. The SCA transaction policies are specified as intents that represent quality of service behavior offered by the JMS binding on an SCA service or reference. However, the SCA JMS binding does not propagate transaction context; therefore, the client and service cannot participate in the same global transaction.

To learn more about SCA global transactions, see the SCA transaction intents documentation.

SCA references can use the `transactedOneWay` intent to transact one-way requests. When the `transactedOneWay` intent is used on an SCA reference, a one-way request on the reference is not sent until the global transaction of the client is committed. If the global transaction of the client is rolled back, the request is not sent.

SCA services can use the `transactedOneWay` intent to transact one-way requests only or the `exactlyOnce` intent to transact both one-way and request-response message patterns. When the `transactedOneWay` intent is used on an SCA service, a one-way request is received from the JMS binding as part of the component's global transaction. When the `exactlyOnce` intent is used on a service, both one-way and request-response message patterns are received from the JMS binding as part of the component's global transaction. The receipt of the message, and the sending of the response for request-response messaging, is not committed until the service transaction commits. If the service transaction is rolled back, the message is again made available for delivery or the message is sent to an exception destination that is based upon the configuration of the bus destination.

The SCA runtime environment typically performs a rollback of a global transaction only if the component produces an unchecked exception error. An unchecked exception error is a subclass of java.lang.RuntimeException or java.lang.Error class. A checked exception does not force a rollback. The component can force a rollback by using the UOWSynchronizationRegistry interface. For example:

```
com.ibm.websphere.uow.UOWSynchronizationRegistry uowSyncRegistry =
    com.ibm.wsspi.uow.UOWManagerFactory.getUOWManager();
uowSyncRegistry.setRollbackOnly();
```

If a reference does not require a `transactedOneWay` intent, then one-way requests are sent immediately. If a service does not require the `transactedOneWay` or `exactlyOnce` intent, requests are removed from the queue prior to the delivery of the request to the component. If the component processing fails, these requests cannot be delivered again.

### Procedure

1. Specify the `transactedOneWay` or `exactlyOnce` intents on your SCA service or reference enable transacting message delivery with the global transaction of your component.

   The following example illustrates the use of the `transactedOneWay` and `exactlyOnce` intents. In this example, the component, `TransactionalComponent`, receives one-way and request-response messages from the DataUpdate service and subsequently sends one-way requests to the loggingService reference transactionally. If the component transaction rolls back, the active request is queued again and any requests to the reference are not sent.

   ```
   <component name="TransactionalComponent">
        <implementation.java class="example.TransactedImpl"
                requires="managedTransaction.global"/>
        <service name="DataUpdate" requires="exactlyOnce">
   ```

```
        <binding.jms>
           <destination name="jms/DataUpdate_Request" type="queue"/>
           <activationSpec name="jms/SCA_JMS_AS"/>
        </binding.jms>
    </service>

    <reference name="loggingService" requires="transactedOneWay">
        <binding.jms>
           <connectionFactory name="jms/SCA_JMS_CF"/>
        </binding.jms>
    </reference>
</component>
```

2. Using the administrative console, configure the bus destination to handle failed messages.
   a. Start the administrative console.
   b. In the navigation pane, click **Service integration** > **Buses** > ***bus_name*** > **Destinations** > ***destination_queue_name*** or ***destination_topic_space_name*** .
   c. Under Exception destination, enter a value for the **Maximum failed deliveries per message** . This value specifies the maximum number of failed attempts to process a message, after which the message is forwarded from its intended destination to the exception destination. This property applies to individual messages.

### Results

You have updated your SCA composite to use transacted message delivery.

## Dynamic JMS resource creation during deployment

The product dynamically creates Java Message Service (JMS) resources necessary for a Service Component Architecture (SCA) composite, if those resources do not exist and relate to the WebSphere default messaging provider. The product creates the resources when adding the SCA composite to a business-level application. The dynamically created resources are created in a WebSphere default messaging provider service integration bus. The product does not create resources that relate to WebSphere MQ; those resources must exist. A dynamically created service integration bus resource is given a name that is specified in the JMS binding or, if the binding does not specify a resource name, is given a default name. When an SCA composite uses a mixture of existing and non-existent resources, the product dynamically creates the resources that do not exist.

**Restriction:** Dynamic resource creation is not supported for multiple-server configurations. For stand-alone application servers, dynamic resource creation is enabled by default. To disable dynamic resource creation, set the `admin.jms.DRC.disable` system property to `true`.

- Default naming of resources
- Deployment validation error or warning messages
- Dynamic resource creation for JMS bindings

### Default naming of resources

When a JMS binding does not specify a Java Naming and Directory Interface (JNDI) name for a resource, the product dynamically creates a service integration bus resource and assigns the resource a default name, `DefaultSCABus`.

**Restriction:** You must have SIBus service enabled for your application server. Before deploying your SCA composite, enable the SIBus service of the server, and then stop and restart the server.

For an SCA service that uses a JMS binding, the product uses the following default names if JNDI name values are not supplied in the composite definition.

*Table 135. Default names for service resources. The product uses the default names when the composite definition omits JNDI name values.*

| Resource | Default name |
|---|---|
| Activation specification | `jms/DefaultSCAActivationSpec` |
| Activation specification create | `ifnotexist` |
| Destination | `jms/<componentName>_<serviceName>_ServiceRequestDestination` |
| Response connection factory name | `jms/DefaultSCAConnectionFactory` |
| Response connection factory create | `ifnotexist` |

The product assigns computed destination names for values that are not provided in the JMS binding element based on the component name and service name, separated with underscores. For example, the computed destination name for a JMS binding in the HelloService service of the HelloServiceComponent component is `jms/HelloServiceComponent_HelloService_ServiceRequestDestination`.

The product assigns the destination a default value only when no JNDI name is supplied in the composite definition and the default activation specification is being used. If the composite definition defines an activation specification that exists already, the destination from the activation specification is used instead of the default value.

For an SCA reference that uses a JMS Binding, the product uses the following default names if JNDI name values are not supplied in the composite definition.

*Table 136. Default names for reference resources. The product uses the default names when the composite definition omits JNDI name values.*

| Resource | Default name |
|---|---|
| Connection factory | `jms/DefaultSCAConnectionFactory` |
| Connection factory create | `ifnotexist` |
| Response connection factory | `jms/DefaultSCAConnectionFactory` |
| Response connection factory create | `ifnotexist` |

The product assigns the response connection factory a default value only when no JNDI name is supplied in the composite definition and the response destination has been defined.

## Deployment validation error or warning messages

The product validates a composite definition when adding an SCA asset to a business-level application. If the validation results in an error, the product does not add the asset to the application. If a warning results, the product issues a warning but adds the asset to the application.

### Errors or warnings from validation of service JMS bindings

When a composite definition sets a `create` attribute to `always` for any of the following service JMS bindings, deployment stops with an error if the resource exists:

- Destination
- Activation specification
- Response destination
- Response connection factory

When a composite definition sets a `create` attribute to `never` for any resource, and that resource does not exist, the product issues a warning but the deployment continues and can complete successfully.

#### Errors or warnings from validation of reference JMS bindings

When a composite definition does not define a callback service or `destination` attribute, deployment stops with an error.

When a composite definition sets a `create` attribute to `always` for any of the following reference JMS bindings, deployment stops with an error if the resource exists:
- Destination
- Connection factory
- Response destination
- Response connection factory

When a composite definition sets a `create` attribute to `never` for any resource, and that resource does not exist, the product issues a warning but the deployment continues and can complete successfully.

An error occurs when an activation specification or connection factory has a default value assigned, and a non-default bus is used. This error can happen if the composite definition has an existing resource defined, such as a destination, and it uses a non-default bus. If the activation specification or connection factory has not been defined, the product supplies the default name.

## Dynamic resource creation for JMS bindings

The product follows patterns for dynamic resource creation that are similar, although different, for services and references.
- Service resource creation
- Reference resource creation

#### Service resource creation

When a service JMS binding is deployed, the product attempts to create resources for the binding. The composite definition might not specify JNDI names for the resources. The resources might not exist. There are four typical patterns for dynamic service resource creation:

**Composite definition does not define resources**

A composite definition that does not define resources resembles:

```
<binding.jms>
</binding.jms>
```

If a composite definition does not define resources, the product does the following:
- Assigns default names to all resources using the default service integration bus.
- Creates the default service integration bus `DefaultSCABus` if it does not exist.
- Creates the default destination `jms/`*`<componentName>`*`_`*`<serviceName>`*`_ServiceRequestDestination` on the default bus.
- Creates the default activation specification `jms/DefaultSCAActivationSpec` if it does not exist and uses the default bus and default destination.
- Creates the default response connection factory `jms/DefaultSCAConnectionFactory` if it does not exist and uses the default bus.

When the product creates a destination, a bus destination and a destination resource are created. The bus destination name and the destination resource name are derived from the JNDI name, with / replaced by _.

**Composite definition defines destination and activation specification**

A composite definition that defines both a destination and an activation specification resembles:

```
<binding.jms>
  <destination name="jms/myDestination_Request" type="queue"/>
  <activationSpec name="jms/myActivationSpec"/>
</binding.jms>
```

If a composite definition defines a destination and activation specification, the product performs actions that depend on whether resources exist for the destination and activation specification.

**Resources for both the destination and activation specification do not exist**

- Creates the default service integration bus `DefaultSCABus` if it does not exist.
- Creates the destination `jms/`*`myDestinationRequest`* on the default bus.
- Creates the activation specification `jms/`*`myActivationSpec`* if it does not exist and uses the default bus and default destination.

**The destination resource does not exist, but the activation specification resource exists**

- Creates the destination `jms/`*`myDestinationRequest`* on the bus that the activation specification uses.

**The destination resource exists, but the activation specification resource does not exist**

- Creates the activation specification `jms/`*`myActivationSpec`* with the bus that the destination uses.

**Composite definition defines the destination only**

A composite definition that defines a destination resembles:

```
<binding.jms>
  <destination name="jms/myDestination_Request" type="queue"/>
</binding.jms>
```

If a composite definition defines a destination, the product performs actions that depend on whether the resource exists for the destination.

**Destination resource does not exist**

- Creates the default service integration bus `DefaultSCABus` if it does not exist.
- Creates the destination `jms/`*`myDestinationRequest`* on the default bus.
- Creates the default activation specification `jms/DefaultSCAActivationSpec` if it does not exist and uses the default bus and the destination `jms/`*`myDestinationRequest`*.

**Destination resource exists**

- The destination must use the default bus. Otherwise, the product returns an error and does not add the asset to the business-level application.
- Creates the default activation specification `jms/DefaultSCAActivationSpec` if it does not exist and uses the default bus and the destination `jms/`*`myDestinationRequest`*.

**Composite definition defines the activation specification only**

A composite definition that defines an activation specification resembles:

```
<binding.jms>
  <activationSpec name="jms/myActivationSpec"/>
</binding.jms>
```

If a composite definition defines an activation specification, the product performs actions that depend on whether a resource exists for the activation specification.

**Activation specification resource does not exist**

- Creates the default service integration bus `DefaultSCABus` if it does not exist.
- Creates the default destination `jms/`*`<componentName>_<serviceName>`*`_ServiceRequestDestination` on the default bus.
- Creates the activation specification `jms/`*`myActivationSpec`* and uses the default bus and default destination.

**Activation specification resource exists**

- Does not create a destination. The run time uses the destination from the existing activation specification.

**Response connection factory for JMS bindings that provide a two-way service**

JMS bindings that provide a two-way service require a response connection factory. When an asset with a two-way service is added to a business-level application, the product behaves in the following manner:

**Composite definition defines the response connection factory**

- Creates the response connection factory if it does not exist.
- If any resources for the binding already exist, creates the response connection factory using the bus that the existing resource uses. Otherwise, the product uses the default bus.
- If other resources for the binding do not exist, creates the other resources using the bus that an existing response connection factory uses.

**Composite definition does not define the response connection factory**

- Assigns the default name `jms/DefaultSCAConnectionFactory` and creates the response connection factory if it does not exist.
- If the product creates a response connection factory using the default name, the response connection factory can only be created on the default bus. Otherwise, the product returns an error and does not add the asset to the business-level application.

  If this error occurs, specify a JNDI name for the response connection factory in the composite definition to correct the error.

**Reference resource creation**

When a reference JMS binding is deployed, the product attempts to create resources for the binding. The composite definition must define a destination. The connection factory, response destination, and response connection factory might not be defined. The resources that are defined might not exist. There are four typical patterns for dynamic reference resource creation:

**Composite definition defines the destination only**

A composite definition that defines a destination resembles:

```
<binding.jms>
  <destination name="jms/myDestination_Request" type="queue"/>
</binding.jms>
```

The destination resource might not exist.

**Destination resource does not exist**

- Creates the default SIBus `DefaultSCABus` if it does not exist.
- Creates the destination `jms/`*`myDestination_Request`* on the default bus.
- Creates the default connection factory `jms/DefaultSCAConnectionFactory` if it does not exist and uses the default bus.

**Destination resource exists**

- Creates the default service integration bus `DefaultSCABus` if it does not exist.
- Creates the default connection factory `jms/DefaultSCAConnectionFactory` if it does not exist and uses the default bus.

**Composite definition defines destination and connection factory**

A composite definition that defines both a destination and a connection factory resembles:

```
<binding.jms>
  <destination name="jms/myDestination_Request" type="queue"/>
  <connectionFactory name="jms/myConnectionFactory"/>
</binding.jms>
```

Each of these resources might not exist.

**Resources for both the destination and connection factory do not exist**

- Creates the default service integration bus `DefaultSCABus` if it does not exist.

- Creates the destination `jms/myDestination_Request` on the default bus.
- Creates the connection factory `jms/myConnectionFactory` if it does not exist and uses the default bus and default destination.

**The destination resource exists, but the connection factory resource does not exist**

- Creates the connection factory `jms/myConnectionFactory` with the bus that the destination uses.

**The destination resource does not exist, but the connection factory resource exists**

- Creates the destination `jms/myDestination_Request` on the bus that the connection factory uses.

## Invoking operations using JMS binding operation selection

You can invoke an operation using JMS binding operation selection. By default, a JMS binding uses the JMS binding operation selection.

### Before you begin

Configure the JMS binding for your SCA application.

### About this task

The JMS binding operation selection is the default binding selection. Thus, this operation selection applies if no operation selection element is specified in the composite definition file. To specify the JMS binding operation selection, add the following operation selection element to the composite definition file:

```
{http://tuscany.apache.org/xmlns/sca/1.0}operationSelector.jmsdefault
```

Specify a JMS binding operation selection on an SCA service interface and on an SCA reference.

### Procedure

1. In a composite definition file, specify a JMS binding operation selection on an SCA service interface.

   Because a given service can define multiple operations, the runtime environment must define mechanisms and algorithms to take a message from a destination bound from an SCA service using the SCA JMS binding, and invoke the correct operation on the SCA service implementation.

   The JMS binding defines a `String` message property called `scaOperationName`. When receiving a request at a service, or a callback at a reference, the JMS binding uses the following algorithm to determine the operation name:

   a. If there is only one operation on the service interface, it is assumed that this operation is the operation name for the request.
   b. Otherwise, if the JMS property `scaOperationName` is set, the value of this property is used as the operation name.
   c. Otherwise, if the message is a JMS text or bytes message containing XML, then the selected operation name is taken from the local name of the root element of the XML payload. This operation selection behavior is only supported over the jmsdefault and the jmsTextXML and jmsBytesXML wire formats.
   d. Otherwise, it is assumed that the operation name is `onMessage`.

2. In a composite definition file, specify a JMS user property operation selection on an SCA reference.

   When using the JMS user operation selector on the service side, the reference side or service side callback must set the matching JMS user property. In the service-side example, the operation selector uses the value of the `jmsTestUserProp` to determine the target operation. You can set this property for the reference or callback side by specifying one or more header properties in the `operationProperties` element; for example:

```
<operationProperties name="proxyMethodName">
<headers>
<property name="jmsTestUserProp">remoteMethodName</property>
</headers>
</operationProperties>
```

In the example, a call to the `proxyMethodName` on the reference side sets the `jmsTestUserProp` user property to `remoteMethodName`. The `proxyMethodName` target operation is set to `remoteMethodName` when the service-side operation selector is configured as in the previous step.

### Results

You have configured a JMS binding operation selection.

### What to do next

Deploy and test the operation selection in your SCA application.

## Invoking operations using JMS user property operation selection

You can invoke an operation using JMS user property operation selection.

### Before you begin

Configure the JMS binding for your SCA application.

### About this task

The JMS user property operation selection is a predefined operation selector that determines the target operation from the value of a given JMS user property. You can define the name of the JMS user property using the `propertyName` attribute of the `operationSelector.jmsUserProp` element. To specify the JMS user property operation selection, add the following operation selection element to the composite definition file:

```
{http://tuscany.apache.org/xmlns/sca/1.0}operationSelector.jmsUserProp
```

Specify a JMS user property operation selection on an SCA service interface and on an SCA reference.

### Procedure

1. In a composite definition file, specify a JMS user property operation selection on an SCA service interface.

   On the service side, the `jmsUserProp` operation selection uses the value of the given JMS user property to determine the target operation. For example:

   ```
   <binding.jms>

   ...
       <ts:operationSelector.jmsUserProp propertyName="jmsTestUserProp"/>
   ...
   </binding.jms>
   ```

   The operation selector requires that you set a JMS user property to the target operation name. If the property is not set or there is no matching operation, the operation selector does not default to any other value, unlike the default JMS binding operation selector.

2. In a composite definition file, specify a JMS user property operation selection on an SCA reference.

   When using the JMS user operation selector on the service side, the reference side or service side callback must set the matching JMS user property. In the service-side example, the operation selector uses the value of the `jmsTestUserProp` to determine the target operation. You can set this property for the reference or callback side by specifying one or more header properties in the `operationProperties` element; for example:

```
<operationProperties name="proxyMethodName">
  <headers>
    <property name="jmsTestUserProp">remoteMethodName</property>
  </headers>
</operationProperties>
```

In the example, a call to the `proxyMethodName` on the reference side sets the `jmsTestUserProp` user property to `remoteMethodName`. The `proxyMethodName` target operation is set to `remoteMethodName` when the service-side operation selector is configured as in the previous section.

### Results

You have configured a JMS user property operation selection.

### What to do next

Deploy and test the operation selection in your SCA application.

## Invoking operations using custom operation selectors

If your application cannot use a default JMS binding operation selection or JMS user property operation selection to determine the target operation, you can use a JMS custom operation selector to invoke operations.

### Before you begin

Configure the JMS binding for your SCA application.

It is recommended that your SCA component implementations contain only business logic to improve their portability, such as over other bindings. To improve portability, use the custom operation selector to hold the JMS-specific logic that handles an incoming JMS Message, enabling the component implementation to focus on binding-neutral business logic.

### About this task

You can configure a JMS custom operation selector in an SCA composite definition without any changes to the application. To specify the JMS custom operation selection, add the following operation selection element to the composite definition file:

```
{http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06}operationSelector.jmsCustom
```

The custom operation selector must implement the following interface:

```
package com.ibm.websphere.soa.sca.operationselector.jms.OperationSelector;
import javax.jms.Message;

public interface OperationSelector {
  public String getOperationName(Message msg);
  public WireFormatContext getWireFormatContext();
  public void setWireFormatContext(WireFormatContext ctx);
```

The interface exposes an instance of javax.jms.Message and enables interaction with the JMS user properties and message body. After doing operation selection, you do not need to use the `reset()` method to reposition the byte stream cursor for a BytesMessage. The run time automatically resets the cursor in all cases so that the wire format handler is not impacted by the operation selector reading the message first.

If the message body of a BytesMessage is read using any of the `read` methods available on a BytesMessage, reposition the byte stream to the beginning using the `reset()` method so that message processors can read the data in the entire message body intended for the targeted operation.

The wire format context is held by an instance of the com.ibm.websphere.soa.sca.wireformat.WireFormatContext class, which is passed with each invocation.

The WireFormatContext class provides a java.util.Map interface where you can set property key and value pairs in the context. The WireFormatContext interface also provides several methods to extract useful information about the current context such as component and service names, invocation types, and the ability to mark exceptions. Refer to the Java documentation for the com.ibm.websphere.soa.sca.wireformat.WireFormatContext interface for a complete list of methods.

## Procedure

1. In a composite definition file, configure a custom operation selector.

   Use the `operationSelector.jmsCustom` element and the `class` attribute to identify the customer operation selection implementation class. The custom operation selector applies when receiving a request at a service, or a callback at a reference.

```
<component name="AccountComponent">
  <implementation.java ...>
  <service name="AccountService">
    <binding.jms>
      <destination ...>
      <response>
      ...
      </response>
      <xmlns:fep="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
                fep:operationSelector.jmsCustom
                class="com.ibm.test.soa.sca.opsel.SimpleCustomOpSel"/>
    </binding.jms>
  </service>
</component>
```

2. Write code that implements the JMS custom operation selector class.

   For the SimpleCustomOpSel example class, you can use code such as the following:

```
package com.ibm.test.soa.sca.opsel;

import com.ibm.websphere.soa.sca.operationselector.jms.OperationSelector.*;
import javax.jms.*;

public class SimpleCustomOpSel implements OperationSelector {

    private WireFormatContext opSelContext;

    @Override
    public String getOperationName(Message msg) {
        String retVal = computeOperationName(msg);
        return retVal;
    }

    @Override
    public WireFormatContext getWireFormatContext() {
        return opSelContext;
    }

    @Override
    public void setWireFormatContext(WireFormatContext ctx) {
        this.opSelContext = ctx;
    }

    /*
     * There is a pre-packaged operationSelector that can do this,
     * <ts:operationSelector.jmsUser>.
     */
     private String computeOperationName(Message msg) {
         String opName = null;
         Integer val = null;
         try {
             val = msg.getIntProperty("MyPropertyName");
             if (val.equals(Integer.valueOf("1"))) {
                 opName = "addOperation";
             } else if (val.equals(Integer.valueOf("2"))) {
...
```

## Results

You have configured a custom operation selector.

## What to do next

Package the operation selection implementation class with your application. The class must be loadable by an application-level class loader.

Deploy and test the operation selector in your SCA application.

# Using Atom bindings in SCA applications

You can use an Atom binding in a Service Component Architecture (SCA) application to expose collections of data as an Atom feed or to reference existing external Atom feeds.

## Before you begin

If you are unfamiliar with the Atom protocol, refer to documentation on the Atom Syndication Format, an XML-based document format that describes web feeds, and the Atom Publishing Protocol, a protocol for publishing and updating web resources.

## About this task

Use the Atom binding to work with services that provide or consume entries described in the Atom Syndication Format and Atom Publishing Protocol. An SCA component can reference existing external web feeds defined using the Atom protocol and work with them inside a Java implementation. Also, you can use the Atom binding to compose new services and expose them as an Atom feed.

This topic describes the following procedures:

- Expose an Atom feed service using an Atom binding.
- Use an Atom binding reference to access services exposed by SCA applications using the Atom binding or to access external Atom feeds.

## Procedure

- Expose an Atom feed service using an Atom binding.
  1. Configure the Atom feed service in an SCA composite definition.

     Specify the uniform resource identifier (URI) of the Atom feed in a service in the composite definition of an SCA composite. The following example of a composite definition has a service exposed over the Atom binding:

```
<component name="NewsServiceComponent">
  <implementation.java class="com.ibm.test.atom.NewsServiceImpl"/>
  <service name="NewsService">
    <t:binding.atom uri="http://localhost:9080/newsService"/>
  </service>
</component>
```

     The example Atom binding URI, `http://localhost:9080/newsService`, is an absolute URI. To run applications that use an Atom binding in product clusters, specify a relative URI; for example:

```
<t:binding.atom uri="/newsService"/>
```

  2. Access the service.

     For example, to access the `NewsService` service, either use an SCA reference in another component or directly access the URI `http://localhost:9080/newsService` from a web browser. If accessed from a web browser, the browser handles the output as an Atom feed.

     The following example shows XML tagging for an Atom feed returned from the `NewsService` service:

```
<?xml version="1.0" encoding="UTF-8"?>
<feed xmlns="http://www.w3.org/2005/Atom">
  <title type="text">Feed</title>
  <id>Feed1329090360</id>
  <entry>
    <id>Item1</id>
    <title type="text">item</title>
    <content type="application/xml">
      <ns2:root xmlns:ns2="http://tuscany.apache.org/xmlns/sca/databinding/jaxb/1.0"
          xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" xsi:type="item">
      <name xmlns="">First Item Name</name>
      <title xmlns="">First Item Title</title>
    </ns2:root>
  </content>
  <link href="Item1"></link>
 </entry>
</feed>
```

3. Manipulate the Atom feed using HTTP actions.

   You can manipulate the collections of items exposed by an Atom service by using the four basic actions of the HTTP protocol:
   – POST (create or add)
   – GET (retrieve or query)
   – PUT (update)
   – DELETE (remove)

   The Java implementation class for the component should implement the org.apache.tuscany.sca.data.collection.Collection interface or an interface that extends the Collection interface. The following methods are defined in the org.apache.tuscany.sca.data.collection.Collection interface:

   **public abstract Entry[] getAll()**
   Returns every entry in the feed

   **public abstract Entry[] query(String s)**
   Queries the feed for entries based on some matching criteria

   **public abstract Object post(Object obj, Object obj1)**
   Adds a new entry to the feed

   **public abstract Object get(Object obj) throws NotFoundException**
   Returns a single entry identified by the provided key value.

   **public abstract void put(Object obj, Object obj1) throws NotFoundException**
   Updates an existing entry identified by the provided key value

   **public abstract void delete(Object obj) throws NotFoundException**
   Deletes an existing entry identified by the provided key value

- Use an Atom binding reference to access services exposed by SCA applications using the Atom binding or to access external Atom feeds.

  1. Configure an Atom binding reference to access an exposed service.

     Specify a reference in the composite definition of an SCA composite that accesses an exposed service. The following example is a reference definition that accesses the `NewsService` service:

```
<reference name="newsServiceRef" target="NewsServiceComponent/NewsService">
    <t:binding.atom/>
</reference>
```

  2. Configure an Atom binding reference to access an external Atom feed.

     Specify a reference in the composite definition of an SCA composite that accesses an external Atom feed, for example:

```
<reference name="atomFeed">
    <tuscany:binding.atom uri="http://feeds.feedburner.com/blogspot/Dcni?format=xml"/>
</reference>
```

  3. Work with the Atom binding reference inside a Java implementation.

     A Java implementation class for an SCA component that contains the two example references might define them as follows:

```
@Reference(required = false)
public Collection newsServiceRef;

@Reference(required = false)
public Collection atomFeed;
```

  4. Use the Collection API in the implementation to manipulate the feed.

     For example, to add a new entry to the `NewsService` feed, the implementation might call:

```
MyEntry entry = new MyEntry("Title", "Content");
newsServiceRef.post("mykey-10-15", entry);
```

     To retrieve an entry from the external feed, the implementation code might use the following example code:

```
atomFeed.get("idtag-20090321");
```

## What to do next

Deploy your SCA component in an application.

If the Atom feed service is deployed to a cluster and the target attribute, @target, is used to point to the service, the target URI resolves to an HTTP port for an individual cluster member. To maintain failover and load balancing in this situation, you can use an absolute URI on the `binding.atom` element that points to a proxy server endpoint rather than the target attribute on the reference element. For more information, see the topics on resolving SCA references and on routing HTTP requests to an SCA service when using an external web server.

## Securing data exposed by Atom bindings

You can secure collections of data that are exposed by an Atom binding in a Service Component Architecture (SCA) application. An Atom binding can expose data as an Atom feed or reference existing external Atom feeds.

### Before you begin

If you are unfamiliar with the Atom protocol, refer to documentation on the Atom Syndication Format, an XML-based document format that describes web feeds, and the Atom Publishing Protocol, a protocol for publishing and updating web resources.

For information about using Atom bindings in this product, refer to “Using Atom bindings in SCA applications” on page 1101.

**transition:** In Version 8.0, the default value for the web authentication property `webAuthReq` is `persisting`, which enables credential persistence that allows login information to be available to unprotected web clients and enables additional access to user information. You must set the `webAuthReq` property to `lazy` to prevent unprotected web clients additional access to user information through persisting credentials. For more information, see Security hardening features enablement and migration. You can set `webAuthReq` to lazy on the administrative console Web security - General settings page:

1. Click **Security** > **Global security** > **Authentication** > **web and SIP security** > **General settings**.
2. Select **Authenticate only when the URI is protected**, which enables lazy authentication.
3. Click **Apply**.

For more information, see Web authentication settings.

### About this task

Use the Atom binding to work securely with services that provide or consume entries described in the Atom Syndication Format and Atom Publishing Protocol.

### Procedure

1. Configure the Atom feed service security in an SCA composite definition.

   You can secure services that are exposed over an Atom binding using intents. Administrative and application security must be enabled for the intents to be enforced. The following three intents are valid options for the `requires` attribute on the `binding.atom` element:

   **authentication.transport**
   Requires any client invoking the service to provide valid authentication information

   **confidentiality.transport**
   Requires any client invoking the service to do so over a secure transport that provides confidentiality of the transport

   **integrity.transport**
   Requires any client invoking the service to do so over a secure transport that provides integrity of the transport

Edit a composite definition that exposes a Java service over the Atom binding so that the exposed service requires a client to authenticate and communicate over a secure transport; for example:

```
<component name="NewsServiceComponent">
  <implementation.java class="test.abdera.NewsServiceImpl"/>
  <service name="NewsService">
    <t:binding.atom uri="/NewsServiceComponent/newsService"
        requires="authentication.transport confidentiality.transport"/>
  </service>
</component>
```

For information about authorization policy, refer to documentation on SCA authorization and security identity policies.

2. Invoke a secure service that is exposed over an Atom binding.

   You can access the service directly from a browser or a client that supports Atom feeds. To access the feed directly, you can use the uniform resource indicator (URI) that the service specifies.

   If the service requires confidentiality or integrity, use the https protocol. If the service requires authentication, the user is prompted by the browser to enter valid credentials. If a Java client is used to access the service, include the authentication information in the HTTP header.

   The following example invokes a service using a reference URI. If the service being referenced requires confidentiality or integrity, use the https protocol.

```
<reference name="atomFeed">
    <tuscany:binding.atom uri="https://localhost:9443/newsService"/>
</reference>
```

You can also invoke the service using a reference target:

```
<reference name="atomFeed" target="NewsServiceComponent/NewsService">
    <tuscany:binding.atom/>
</reference>
```

For this example, the invocation is secure only if the service specifies the `confidentiality.transport` or `integrity.transport` intent.

To authenticate when invoking a service over an Atom binding, you have two options:

- Use single sign-on (SSO) to authenticate.

  If SSO is enabled and there has been a successful authentication before, the credentials are propagated with the request. For information about enabling SSO, see the topic on implementing single sign-on to minimize web user authentications.

- Configure an authentication-alias, and send a specific user name and password with the request.

  You can use this option for references in `implementation.java` components. This option is not supported for references in `implementation.widget` components.

  a. Create an authentication-alias using the administrative console Java 2 Connector (J2C) authentication data entry page or wsadmin commands. See topics on J2C authentication data entries.

  b. In the composite definition, define the product SCA namespace and specify the alias name on the `binding.atom` element using the `authentication-alias` attribute.

```
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
...
xmlns:qos="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
...
<reference name="atomFeed" target="NewsServiceComponent/NewsService">
    <tuscany:binding.atom qos:authentication-alias="AtomAlias"/>
</reference>
```

### What to do next

Test the service security.

## Using Widget implementation in JavaScript with Atom bindings

The JavaScript code in an HTML file can use Service Component Architecture (SCA) references that are defined in a Tuscany Widget implementation. Use Widget implementation to work with data in Atom collections that an SCA service returns in JavaScript.

## Before you begin

You can use an Atom binding in an SCA application to expose collections of data as an Atom feed or to reference existing external Atom feeds. If you are unfamiliar with the Atom protocol, refer to documentation on the Atom Syndication Format, an XML-based document format that describes web feeds, and the Atom Publishing Protocol, a protocol for publishing and updating web resources.

## About this task

An SCA component can define SCA references for use in JavaScript code. Use Tuscany Widget implementation to define the references. The implementation supports references that use an Atom binding, and does not support the definition of SCA services.

The SCA composite that uses the Widget implementation must be deployed inside a Web application archive (WAR) file.

## Procedure

1. Configure a Widget implementation in an SCA composite definition.

   Create an SCA composite definition file for a component that uses Tuscany `implementation.widget`. For example:

   ```
   <composite>
     <component name="Store">
       <tuscany:implementation.widget location="ui/store.html"/>
          <reference name="shoppingCart">
           <tuscany:binding.atom uri="/ShoppingCart/Cart"/>
          </reference>
     </component>
   </composite>
   ```

   This example defines a Store component that uses Tuscany `implementation.widget` in an HTML file at `ui/store.html`.

2. Enable the SCA reference in an HTML file.

   In the HTML file, `ui/store.html`, define two required script elements that enable SCA references. Specify the following for the first element:

   ```
   <script type="text/javascript>>
        dojo.registerModulePath("tuscany", "/Store/tuscany");
        dojo.require("tuscany.AtomService");
   </script>
   ```

   This definition is required when using Atom binding references. The `dojo.registerModulePath` method tells the `dojo` object where to find requirements in the Tuscany namespace. The first argument is always `"tuscany"`. The second argument is specified in the format */SCA_component_name*`/tuscany`. The `dojo.require` statement for `"tuscany.AtomService"` causes the browser to load the JavaScript file from the `/Store/tuscany/AtomService.js` file. The product dynamically generates this file to connect the Atom binding references to Atom services.

   Specify the following for the second element:

   ```
   <script type="text/javascript" src="/Store/store.js"></script>
   ```

   This definition is required in any HTML file that is used as an implementation for a Widget implementation component. For the script `src` attribute, specify the uniform resource identifier (URI) in the format */SCA_component_name/modified_implementation.widget_location_attribute*; for example, `/Store/store.js`. The modified location attribute is the Widget implementation location attribute without a leading path and with a file extension of `.js`.

3. Define the SCA reference in JavaScript in the HTML file.

   An HTML file that contains the above example reference might resemble:

   ```
   //@Reference
   var catalog = new tuscany.sca.Reference("shoppingCart");
   ```

The //@Reference comment is required. The SCA run time interprets the comment in the same manner that a Java class interprets an @Reference tag.

4. Use JavaScript to manipulate the feed reference.

   For example, to retrieve an entire feed, the HTML file might use the following example code:

   ```
   var items = shoppingCart.get("");
   ```

   To retrieve a single entry, the implementation might call:

   ```
   var item = shoppingCart.get("Item1");
   ```

   To add a new entry to the feed, the HTML file might use the following example code:

   ```
   var entry =
     '<entry xmlns="http://www.w3.org/2005/Atom"><title>item</title><content type="text/xml">'
      + '<Item xmlns="http://services/">' + <name xmlns="">' + itemName + '</name>'
      + '<price xmlns="">' + itemPrice + '</price>' + '</Item>' + '</content></entry>';

   shoppingCart.post(entry);
   ```

### What to do next

Deploy your SCA component in an application.

For additional examples, see the topic on using Widget implementation in JavaScript with Atom or HTTP bindings.

## Using HTTP bindings in SCA applications

You can use an HTTP binding with a wire format of JSON-RPC in a Service Component Architecture (SCA) application to expose services to remote web browser clients. JSON-RPC is a remote procedure call (RPC) protocol encoded in the JavaScript Object Notation (JSON) format.

### About this task

Use the HTTP binding to expose SCA services for consumption by remote web clients. This topic describes how to expose a Java implementation as a service to be consumed by a browser client using native Dojo interfaces and RPC libraries.

To use native SCA references in JavaScript code, see the topic on using Widget implementation in JavaScript with HTTP bindings.

### Procedure

1. Configure the Java service in an SCA composite definition.

   Expose a Java service over the HTTP binding in the composite definition; for example:

```
<composite>
  <service name="EchoService" promote="EchoComponent">
    <interface.java interface="echo.Echo"/>
    <tuscany:binding.http uri="/EchoService"/>
      <tuscany:wireFormat.jsonrpc/>
    </tuscany:binding.http>
  </service>

  <component name="EchoComponent">
    <implementation.java class="echo.EchoComponentImpl"/>
  </component>
</composite>
```

   This example exposes the methods defined in the echo.Echo interface to web browser clients. The echo.EchoComponentImpl class implements the Echo interface and provides the implementation for the component. The service is exposed on the "/EchoService" relative uniform resource identifier (URI).

   The example HTTP binding URI, /EchoService, is a relative URI. To run applications that use an HTTP binding in product clusters, specify a relative URI. You cannot run applications in product clusters if the binding specifies an absolute URI, such as http://localhost:9080/newsService.

2. Access the service from a web browser.

For example, to access the `EchoService` service, use the Dojo toolkit application programming interfaces in an HTML file or JavaServer Pages (JSP) file to access the service available at `/EchoService`:

```
<html>
<head>
<meta http-equiv="Content-Type" content="text/html; charset=ISO-8859-1">
<title>Echo...</title>
<script type="text/javascript" src="./dojo/dojo.js"></script>
<script>
  dojo.require("dojo.io.script")
  dojo.require("dojo.rpc.RpcService")
  dojo.require("dojo.rpc.JsonService")
  dojo.require("dojo.rpc.JsonpService")

  function filladdr(){
    var nameElement=document.getElementById("name");
    var name=nameElement.value;
    var echo = new dojo.rpc.JsonService("/EchoService?smd");
    echo.echo(name).addCallback(fillmsg);
  }

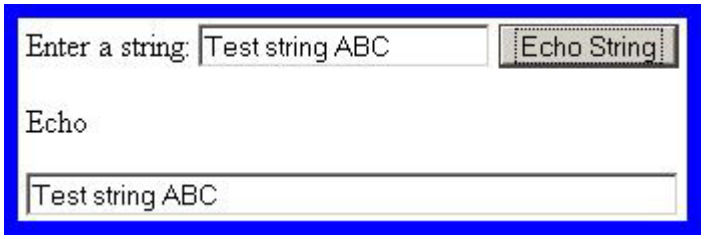
  function fillmsg(result){
    var line=document.getElementById("line1");
    line.value=result;
  }
</script>
</head>
<body>
Enter a string: <input id="name" type="text">
<input type="submit" value="Echo String" onClick="filladdr()"><br>
<p>Echo </p><input id="line1" type="text" size="50"><br><br>
</body>
</html>
```

The URI passed into the dojo.rpc.JsonService constructor `"/EchoService?smd"` contains the query string `"smd"` on the end of the URI specified in the `<binding.http>` definition in the composite. The query string `"smd"` on the end of the URI is required when using Dojo clients.

## Results

The HTML output for the example output shows two text boxes and a `"submit"` button. When a user enters text in the first box and clicks the submit button, the following steps take place:

1. The JavaScript code in the `filladdr()` method obtains the value that was entered in the first text box.
2. The `filladdr()` method instantiates a dojo.rpc.JsonService object pointed to the URI `"/EchoService?smd"`.
3. The JavaScript code runs the `"echo(String)"` method on the JsonService object, causing a JSON-RPC request to be sent to `"/EchoService?smd"`.
4. The SCA run time handles the URI request by running the `EchoComponentImpl.echo(String)` method. The result is returned to the client as an HTTP response.
5. The web client runs the designated callback method, `"fillmsg(result)"`, with the value returned from the service.
6. The JavaScript code in the `fillmsg(result)` method updates the second text box to contain the text returned from the service invocation.



## What to do next

Consider the supported data types for the JSON conversion. Parameters for JSON-RPC requests are sent to the server in JSON format, and must be transformed by the SCA run time for use in the Java implementation. The response to the client is also in JSON format, so the SCA run time converts the value returned from the `EchoComponentImpl.echo()` method back into JSON. For example, `echo("Testing...")` might submit the following data to the server:

```
{"params":["Testing..."],"method":"echo","id":1}
```

The Java method `EchoComponentImpl.echo(String message)` is invoked with the String parameter `"Testing..."` and returns the String object `"echo: Testing..."`. The JSON response returned to the web client might look like:

```
{"id":1,"result":"echo: Testing..."}
```

*Table 137. Supported data types for JSON conversions. Conversion enables the Web client and Java implementation to use the data.*

| | | | | |
|---|---|---|---|---|
| Primitive Type | <==> | JSON | <==> | Primitive Type |
| Array of Primitive Type | <==> | JSON | <==> | Array of Primitive Type |
| Java bean | <==> | JSON | <==> | Java bean |
| List | <==> | JSON | <==> | List |
| Map | <==> | JSON | <==> | Map |
| Set | <==> | JSON | <==> | Set |

# Securing services exposed by HTTP bindings

You can use an HTTP binding with a wire format of JSON-RPC securely in a Service Component Architecture (SCA) application. Use intents to secure services that are exposed by the HTTP binding to remote web browser clients.

## Before you begin

JSON-RPC is a remote procedure call (RPC) protocol encoded in the JavaScript Object Notation (JSON) format.

For information about using HTTP bindings in this product, refer to “Using HTTP bindings in SCA applications” on page 1106.

Enable administrative and application security, if not done so already. To enforce intents to secure services that are exposed by an HTTP binding, administrative and application security must be enabled.

**transition:** In Version 8.0, the default value for the web authentication property `webAuthReq` is `persisting`, which enables credential persistence that allows login information to be available to unprotected web clients and enables additional access to user information. You must set the `webAuthReq` property to `lazy` to prevent unprotected web clients additional access to user information through persisting credentials. For more information, see Security hardening features enablement and migration. You can set `webAuthReq` to lazy on the administrative console Web security - General settings page:

1. Click **Security** > **Global security** > **Authentication** > **web and SIP security** > **General settings**.
2. Select **Authenticate only when the URI is protected**, which enables lazy authentication.
3. Click **Apply**.

For more information, see Web authentication settings.

### About this task

Use the HTTP binding to secure services. To secure services, configure the `requires` attributes on the `binding.http` element.

### Procedure

1. Configure security for the HTTP binding service in an SCA composite definition.

   You can secure services that are exposed over an HTTP binding using intents. The following three intents are valid options for the `requires` attribute on the `binding.http` element:

   **authentication.transport**
   Requires any client invoking the service to provide valid authentication information.

   **confidentiality.transport**
   Requires any client invoking the service to do so over a secure transport that provides confidentiality of the transport.

   **integrity.transport**
   Requires any client invoking the service to do so over a secure transport that provides integrity of the transport.

   Edit a composite definition that exposes a Java service over the HTTP binding so that the exposed service requires a client to authenticate and communicate over a secure transport; for example:

```
<composite>
  <service name="EchoService" promote="EchoComponent">
    <interface.java interface="echo.Echo"/>
    <tuscany:binding.http uri="/EchoService" requires="authentication.transport confidentiality.transport"/>
    <tuscany:wireFormat.jsonrpc/>
    </tuscany:binding.http>
  </service>

  <component name="EchoComponent">
    <implementation.java class="echo.EchoComponentImpl"/>
  </component>
</composite>
```

   For information about authorization policy, refer to topics on SCA authorization and security identity policies.

2. Invoke a secure service that is exposed over an HTTP binding from a web browser.

   You can access the service directly from a JavaServer Pages (JSP) file or HTML page using the Dojo toolkit application programming interfaces from a web browser.

   If the service requires confidentiality or integrity, use the HTTPS protocol. If the service requires authentication, configure the client application to prompt the user for valid user name and password. If the default product settings enable single sign-on (SSO) and the user has authenticated previously, these credentials are automatically propagated in the request to the service.

### What to do next

Test the service security.

## Using Widget implementation in JavaScript with HTTP bindings

The JavaScript code in an HTML file can use Service Component Architecture (SCA) references that are defined in a Tuscany Widget implementation. Use Widget implementation to work with data in JavaScript Object Notation (JSON) format that an SCA service returns in JavaScript.

### Before you begin

You can use the HTTP binding with a wire format of JSON-RPC to expose SCA services for consumption by remote web browser clients. JSON-RPC is a remote procedure call (RPC) protocol encoded in the JSON format.

## About this task

An SCA component can define SCA references for use in JavaScript code. Use Tuscany Widget implementation to define the references. The implementation supports references that use an HTTP binding with a wire format of JSON-RPC, and does not support the definition of SCA services.

The SCA composite that uses the Widget implementation must be deployed inside a web application archive (WAR) file.

## Procedure

1. Configure a Widget implementation in an SCA composite definition.

   Create an SCA composite definition file for a component that uses Tuscany `implementation.widget`. For example:

```
<composite>
  <component name="Store">
    <tuscany:implementation.widget location="ui/store.html"/>
       <reference name="catalog">
         <tuscany:binding.http uri="/Catalog"/>
           <tuscany:wireFormat.jsonrpc/>
         </tuscany:binding.http>
       </reference>
  </component>
</composite>
```

   This example defines a Store component that uses Tuscany `implementation.widget` in an HTML file at `ui/store.html`.

2. Create the HTML file specified in the SCA composite definition for the Widget implementation.

   In the HTML file, define required script elements such as the following:

```
<script type="text/javascript" src="/Store/store.js"></script>
```

   The script `src` attribute points to a JavaScript file that the product dynamically generates to connect the SCA references to their associated services. Specify the uniform resource identifier (URI) in the format */SCA_component_name/modified_implementation.widget_location_attribute*; for example, `/Store/store.js`. The modified location attribute is the location attribute without a leading path and with a file extension of `.js`.

3. Define the SCA reference in JavaScript in the HTML file.

   In the HTML file, define an SCA reference. For example:

```
//@Reference
var catalog = new tuscany.sca.Reference("catalog");
```

4. Add JavaScript code that uses the reference to the HTML file.

   The code used for this example resembles:

```
<script>

  function init() {
    catalog.get().addCallback(catalog_getResponse);
  }

  function catalog_getResponse(items,exception) {
    if(exception){
      alert(exception.message);
      return;
    }
    var catalog = "";
    for (var i=0; i < items.length; i++) {
      var item = items[i].name + ' - ' + items[i].price;
      catalog += '<input name="items" type="checkbox" value="' +
        item + '">' + item + '<br>';
    }
    document.getElementById('catalog').innerHTML=catalog;
  }

</script>
```

   In this example code, the `init` method calls the `get` method on the `catalog` reference. The result is sent to the callback method `callback_getResponse()`. The callback method adds check box elements to the HTML for each item returned from the catalog `get` method.

5. Add the user interface to the HTML file, as needed.

The `ui/store.html` file used for this example might use the following user interface:

```
<html>
<body onload="init()">
<h1>Store</h1>
   <h2>Catalog</h2>
   <form name="catalogForm">
      <div id="catalog"></div>
      <br>
      <input type="button" onClick="addToCart()" value="Add to Cart">
   </form>
</body>
</html>
```

### What to do next

Deploy your SCA component in an application.

When using the Widget implementation, HTTP binding references must be deployed on the same server or cluster as the HTTP binding services that they reference. This limitation is a result of browser limitations on cross-domain JavaScript invocation. If your application defines the reference and service in separate servers or clusters, use a proxy server so that the Widget implementation resource that contains the reference and the HTTP binding service are both accessed using the same HTTP domain.

To resolve HTTP binding references, either use a target attribute, @target, on the reference or specify the URI attribute on the `binding.http` element. For more information, see the topic on resolving SCA references.

For more examples, see the topic on using Widget implementation in JavaScript with Atom or HTTP bindings.

## Using Widget implementation in JavaScript with Atom or HTTP bindings

You can use Tuscany Widget implementation to define Service Component Architecture (SCA) references for use in JavaScript code. Use Widget implementation to work with data that an SCA service returns in JavaScript. The data can be in Atom collections or in JavaScript Object Notation (JSON) format.

### Before you begin

You can use an Atom binding in an SCA application to expose collections of data as an Atom feed or to reference existing external Atom feeds. If you are unfamiliar with the Atom protocol, refer to documentation on the Atom Syndication Format, an XML-based document format that describes web feeds, and the Atom Publishing Protocol, a protocol for publishing and updating web resources.

You can use the HTTP binding with a wire format of JSON-RPC to expose SCA services for consumption by remote web browser clients. JSON-RPC is a remote procedure call (RPC) protocol encoded in the JSON format.

### About this task

An SCA component can define SCA references for use in JavaScript code. Use Tuscany Widget implementation to define the references. The implementation supports references that use an Atom binding or an HTTP binding with a wire format of JSON-RPC, and does not support the definition of SCA services. The implementation also supports the definition of SCA properties.

The SCA composite that uses the Widget implementation must be deployed inside a web application archive (WAR) file.

### Procedure

1. Configure a Widget implementation in an SCA composite definition.

Create an SCA composite definition file for a component that uses Tuscany `implementation.widget`. For example:

```
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
           xmlns:tuscany="http://tuscany.apache.org/xmlns/sca/1.0"
           targetNamespace="http://store" name="storeWidget">
  <component name="Store">
    <tuscany:implementation.widget location="ui/store.html"/>
 </component>
</composite>
```

This example defines a Store component that uses Tuscany `implementation.widget` in an HTML file at `ui/store.html`. The `implementation.widget` definition is located in the `"http://tuscany.apache.org/xmlns/sca/1.0"` namespace, rather than the `"http://www.osoa.org/xmlns/sca/1.0"` namespace that most SCA artifacts use.

2. Add SCA reference definitions to the SCA composite definition.

   Define one or more references that use an Atom binding or an HTTP binding. An SCA reference that uses an Atom binding resembles:

   ```
   <reference name="shoppingCart">
       <tuscany:binding.atom uri="/ShoppingCart/Cart"/>
   </reference>
   ```

   An SCA reference that uses the HTTP binding with a wire format of JSON-RPC resembles:

   ```
   <reference name="catalog">
       <tuscany:binding.http uri="/Catalog"/>
         <tuscany:wireFormat.jsonrpc/>
       </tuscany:binding.http>
   </reference>
   ```

   For more information on the Atom binding references, see the topics on using Atom bindings. For more information on HTTP binding references, see the topics on using HTTP bindings.

3. Add SCA property definitions to the SCA composite definition.

   You can define one or more properties in the SCA composite definition file. For example:

   ```
   <property name="currency">USD</property>
   ```

4. Add the SCA composite definition to the WAR file.

   Save the SCA composite definition in the `META-INF/sca-deployables/default.composite` file in the WAR file.

   For the example in this topic, the complete composite file is as follows:

   ```
   <composite xmlns="http://www.osoa.org/xmlns/sca/1.0"
              xmlns:tuscany="http://tuscany.apache.org/xmlns/sca/1.0"
              targetNamespace="http://store" name="storeWidget">
     <component name="Store">
       <tuscany:implementation.widget location="ui/store.html"/>

         <reference name="shoppingCart">
             <tuscany:binding.atom uri="/ShoppingCart/Cart"/>
         </reference>
         <reference name="shoppingTotal">
             <tuscany:binding.http uri="/ShoppingCart/Total">
               <tuscany:wireFormat.jsonrpc/>
             </tuscany:binding.http>
         </reference>
         <reference name="catalog">
             <tuscany:binding.http uri="/Catalog"/>
               <tuscany:wireFormat.jsonrpc/>
             </tuscany:binding.http>
         </reference>

         <property name="currency">USD</property>

     </component>
   </composite>
   ```

5. Create the HTML file specified in the SCA composite definition for the Widget implementation and add it to the WAR file.

   In the HTML file, define the SCA references and properties and define required script elements as described in topics on using Atom bindings or HTTP bindings. The `ui/store.html` file used for this example resembles:

```
<html>
<head>
<title>Store</title>

<script type="text/JavaScript" src="../dojo/dojo.js"></script>
<script type="text/javascript>>
     dojo.registerModulePath("tuscany", "/Store/tuscany");
     dojo.require("tuscany.AtomService");
     dojo.require("dojo.rpc.JsonService");
</script>
<script type="text/JavaScript" src="/Store/store.js"></script>
<script language="JavaScript">

  //@Reference
  var catalog = new tuscany.sca.Reference("catalog");

  //@Reference
  var shoppingCart = new tuscany.sca.Reference("shoppingCart");

  //@Property
  var currency = new tuscany.sca.Property("currency");

  var catalogItems;

  function catalog_getResponse(items,exception) {
    var catalog = "";
    for (var i=0; i < items.length; i++) {
      var item = items[i].name + ' - ' + items[i].price;
      catalog += '<input name="items" type="checkbox" value="' +
        item + '">' + item + '<br>';
    }
    document.getElementById('catalog').innerHTML=catalog;
    catalogItems = items;
  }

  function shoppingCart_getResponse(feed) {
    if (feed != null) {
       var entries = feed.getElementsByTagName("entry");
       var list = "";
       for (var i=0; i < entries.length; i++) {
         var content =
           entries[i].getElementsByTagName("content")[0];
         var name =
           content.getElementsByTagName("name")[0].firstChild.nodeValue;
         var price =
           content.getElementsByTagName("price")[0].firstChild.nodeValue;
         list += name + ' - ' + price + '<br>';
       }
     }
     document.getElementById("shoppingCart").innerHTML = list;
   }

   function shoppingCart_postResponse(entry) {
     shoppingCart.get("").addCallback(shoppingCart_getResponse);
   }

   function addToCart() {
     var items  = document.catalogForm.items;
     var j = 0;
     for (var i=0; i < items.length; i++) {
       if (items[i].checked) {
```

```
            var entry =
              '<entry xmlns="http://www.w3.org/2005/Atom"><title>item<content
              type="text/xml">' + '<Item xmlns="http://services/">' + '<name xmlns="">'
              + catalogItems[i].name + '</name>' + '<price xmlns="">' +
              catalogItems[i].price + '</price>' + '</item>' + '</content></entry>';

            shoppingCart.post(entry).addCallback(shoppingCart_postResponse);
            items[i].checked = false;
          }
        }
      }

      function init() {
        catalog.get().addCallback(catalog_getResponse);
        shoppingCart.get("").addCallback(shoppingCart_getResponse);
      }
    </script>
    </head>

    <body onload="init()">
    <h1>Store</h1>
     <div id="store">
       <h2>Catalog</h2>
       <form name="catalogForm">
          <div id="catalog"></div>
          <br>
          <input type="button" onClick="addToCart()" value="Add to Cart">
       </form>
       <br>
       <h2>Your Shopping Cart</h2>
       <form name="shoppingCartForm">
          <div id="shoppingCart"></div>
          <br>
          <div id="total"></div>
          <br>
       </form>
     </div>
    </body>
    </html>
```

### What to do next

Deploy your SCA component in an application.

## Resolving SCA references

During application assembly or deployment, a reference (a service dependency) is typically resolved to an actual deployed SCA service.

### About this task

There are two ways to resolve a Service Component Architecture (SCA) reference:

- Using the @target attribute in order to resolve a reference to a component service within the domain
- Using a binding-specific endpoint using the @uri attribute of the binding element

**Resolving an SCA reference using the @target attribute**

Use this option when the target service is another SCA service that is in the same domain as the client component, or rather, the component with the reference.

When you have configured the SCA default binding for your SCA service, the @target attribute is typically used to resolve an SCA client reference to the SCA component service. You can also use the @target attribute to resolve an SCA reference when using the SCA non-default bindings. Using this mechanism, the client does not need to know the endpoint of a service that is calculated

during run time in order to resolve to it. Whereas a binding-specific endpoint can contain server-specific information such as an Hypertext Transfer Protocol (HTTP) port for a web service binding, the @target attribute does not require an update when the client-service pair is deployed to a new server with different ports. You can also redeploy a target service within the domain from a single server to a cluster without requiring a change to the reference-side composite definition. If you use this approach, remember that you must use bindings of the same type, meaning that the reference must share a common binding with the service it is targeting.

**Resolving an SCA reference using a binding-specific endpoint**

You must resolve an SCA reference using a binding-specific endpoint if you invoke non-SCA services over non-default bindings or if you have compatible SCA services that are hosted in another domain.

In general, obtain the binding-specific endpoint from the service provider.

If your target service is another SCA service, see the documentation for configuring the particular SCA binding to learn more about which binding-specific endpoint is used for a given service deployment over a particular binding.

## Procedure

1. Determine from the service provider whether the service that you are consuming is an SCA service within the same domain as your client.
2. Determine the binding that your client uses to consume this service.

   If the target service is an SCA service, the binding that you use is based on the bindings over which the service is exposed. If the service is not an SCA service, the binding depends on the technology over which the service is provided. For example, services offered over SOAP/HTTP use the SCA web services binding.
3. If the SCA service is hosted in the same domain as your client, use the @target attribute to resolve a reference to a component service within the domain.

   The following examples demonstrate using the @target attribute. The syntax for the `<reference>` element is the same for the different SCA binding types.

   - SCA default binding

     Target component

```
<component name="TargetComponent">
  <service name="BankService"/>
</component>
```

     Client component

```
<component name="ClientComponent">
  <reference name="myReference" target="TargetComponent"/>
</component>
```

   - SCA Web Services Binding

     Target component

```
<component name="TargetComponent">
  <service name="BankService">
    <interface.wsdl ....>
    <binding.ws/>
  </service>
</component>
```

     Client component

```
<component name="ClientComponent">
  <reference name="myReference" target="TargetComponent">
    <interface.wsdl ....>
    <binding.ws/>  <!-- The client does not have to specify endpoint details. -->
  </reference>
</component>
```

   - SCA Atom binding

     Target component

```
<component name="NewsServiceComponent">
  <service name="NewsService">
    <t:binding.atom uri="/newsService"/>
  </service>
</component>
```

Client component

```
<component name="NewsComponent">
  <reference name="newsServiceRef" target="NewsServiceComponent/NewsService">
    <t:binding.atom/> <!-- The client does not need to specify endpoint details -->
  </reference>
</component>
```

- SCA HTTP binding

  Target component

```
<component name="Catalog">
  <service name="Catalog">
    <t:binding.http>
      <t:wireFormat.jsonrpc/>
    </t:binding.http>
  </service>
</component>
```

Client component

```
<component name="Store">
   <t:implementation.widget location="store.html"/>
   <reference name="catalog" target="Catalog/Catalog">
      <t:binding.http/> <!-- The client does not need to specify endpoint details -->
         <t:wireFormat.jsonrpc/>
      </t:binding.http>
   </reference>
</component>
```

4. Resolve the SCA reference by using a binding-specific endpoint if you are invoking non-SCA services over non-default binding or if you have compatible SCA services that are hosted in another domain.

   The following examples demonstrate using the binding-specific endpoint for the client component:

   - SCA web service client component

```
<component name="ClientComponent">
  <reference name="myReference">
      <!-- The exact URL is obtained from a service provider. -->
    <binding.ws uri="http://www.mybank.com:9080/MyBank/AccountService/services>
  </reference>
</component>
```

   - SCA binding.atom client component

```
<component name="Aggregator">
  <reference name="atomFeed1">
    <t:binding.atom
      uri="http://www.ibm.com/developerworks/views/webservices/rss/libraryview.jsp"/>
  </reference>
</component>
```

   - SCA binding.http client component

```
<component name="Store">
  <reference name="catalog">
    <t:binding.http uri="/catalog">
      <t:wireFormat.jsonrpc/>
    </t:binding.http>
  </reference>
</component>
```

   See the documentation for configuring the particular SCA binding to learn more about binding-specific endpoint resolution for these SCA binding types.

### Results

You have identified your SCA client's reference to a target service that it will consume.

## Routing HTTP requests to an SCA service when using an external web server

If you are using an external web server to route requests to an SCA service that is exposed over the SCA web services, Atom or HTTP binding, you must define the endpoints of the SCA service to the Web Server HTTP plug-in.

## About this task

Requests to services that are exposed over the SCA binding that use the proxy server type that is provided with WebSphere Application Server are routed over the specified proxy by default.

However, if your configuration uses an external web server with the HTTP plug-in for WebSphere Application Server and you want requests to services that are exposed over the SCA binding to route through the external web server, you must define the endpoints for the SCA service by adding the service URL patterns to the `plugin-cfg.xml` file for the Application Server.

## Procedure

1. Obtain the URL patterns for each service.

   You can obtain the URL patterns in one of the following ways:

   - Use the message, which is located in the server log file, that indicates the web application is successfully created.

     During service startup, for each service that is exposed over an SCA binding, a dynamic web application is created and configured with the URI of the service. This process is described as an informational message within the server log file as shown in the following example.

     In the following example message, the helloworldws composition unit contains the AsyncTranslatorService service, which is exposed over the SCA web service binding. This message provides the necessary context root and URL pattern for the service, which you must add to the `plugin-cfg.xml` file.

```
/AsynchTranslatorComponent/AsynchTranslatorService/*

[[11/18/08 10:10:52:156 EST] 00000070 servlet I com.ibm.ws.webcontainer.servlet.ServletWrapper init
SRVE0242I: [helloworldws]
[/AsynchTranslatorComponent/AsynchTranslatorService]
[SCA_WS_BINDING_IMPL_CLASS_PLACEHOLDER]: Initialization successful.
[11/18/08 10:10:52:156 EST] 00000070 WASAxis2Exten I
WSWS7037I: The /* URL pattern was configured for the SCA_WS_BINDING_IMPL_CLASS_PLACEHOLDER servlet located
in the SCAWSBindSERV_AsynchTranslatorComponent_AsynchTranslatorService.war web module.
```

   - Use the `warinfo.props` WebSphere configuration repository file.

     For each composition unit that has at least one service or reference exposed over the binding, a single `warinfo.props` file is generated during deployment. This file contains configuration information for each dynamic web application that starts during the server startup process.

     The `warinfo.props` file is located in, for example, the *profile_root*`\SOAAppSrv01\config\cells\cell1\cus\helloworldws\cver\BASE\meta\warinfo.props` directory.

     The file contains an entry for each dynamic web application. For example:

```
#
#Tue Nov 18 10:10:37 EST 2008
SCAWSBindSERV_AsynchTranslatorComponent_
AsynchTranslatorService.war=AsynchTranslatorComponent/
AsynchTranslatorService\:default_host\:false\:false\:false
```

     The value immediately following the `war=` and ending prior to the `\:` is the context root for the web application. In this example, the context root is **AsynchTranslatorComponent/AsynchTranslatorService**.

2. Add the values for each dynamic web application to the `plugin-cfg.xml` file.

   After obtaining all of the entries from each of the services that you want to define to the proxy server, add the values to the `plugin-cfg.xml` file. It is important that you add the URI to the specific UriGroup that contains a server and hosts the proxied service because multiple UriGroups might exist. If this process is not done correctly, an HTTP 404 message results.

   In the following example, see the **AsynchTranslatorComponent/AsynchTranslatorService** entry that has been added to the list of URI patterns:

```
<UriGroup Name="default_host_Cluster2_URIs">
? <Uri AffinityCookie="JSESSIONID"
AffinityURLIdentifier="jsessionid"
Name="/IBM_WS_SYS_RESPONSESERVLET/*" />
?  <Uri AffinityCookie="JSESSIONID"
```

```
AffinityURLIdentifier="jsessionid"
Name="/IBM_WS_SYS_RESPONSESERVLET/*.jsp" />
?  <Uri AffinityCookie="JSESSIONID"
AffinityURLIdentifier="jsessionid"
Name="/IBM_WS_SYS_RESPONSESERVLET/*.jsv" />
?  <Uri AffinityCookie="JSESSIONID"
AffinityURLIdentifier="jsessionid"
Name="/IBM_WS_SYS_RESPONSESERVLET/*.jsw" />
?  <Uri AffinityCookie="JSESSIONID"
AffinityURLIdentifier="jsessionid"
Name="/IBM_WS_SYS_RESPONSESERVLET/j_security_check" />
?  <Uri AffinityCookie="JSESSIONID"
AffinityURLIdentifier="jsessionid"
Name="/IBM_WS_SYS_RESPONSESERVLET/ibm_security_logout" />

?  <Uri AffinityCookie="JSESSIONID"
AffinityURLIdentifier="jsessionid"
Name="/AsynchTranslatorComponent/AsynchTranslatorService/*" /> </UriGroup>
```

### Results

You have configured the endpoints for SCA services to route requests through an external web server configured with the HTTP plug-in for WebSphere Application Server

## Interoperability between Open SCA client services and WebSphere Process Server SCA modules

Support for Service Component Architecture (SCA) provides a simple, yet powerful programming model for constructing applications based on the Open SCA specifications. The SCA modules of WebSphere Process Server use import and export bindings to interoperate with Open SCA services.

An Open SCA application invokes WebSphere Process Server SCA applications using an export binding. An Open SCA application receives a call from a WebSphere Process Server SCA application using an import binding.

When building an Open SCA service client which will invoke WebSphere Process Server SCA module services, start with an existing WSDL file for all supported bindings except Enterprise JavaBeans (EJB) bindings.

Generate Java interfaces from the Web Services Description Language (WSDL) file. Do not port modules from WebSphere Process Server SCA to Open SCA and do not port modules from Open SCA to WebSphere Process Server SCA.

In general, Java artifacts are not reusable across WebSphere Process Server SCA modules and Open SCA applications, even when one artifact invokes the other over a common WSDL interface. You must use appropriate tooling to separately generate, from the WSDL interface, the Java interfaces and classes that are used in the Open SCA applications and the Java interfaces and classes that are used in the WebSphere Process Server SCA modules. For Open SCA applications, use the wsimport command-line tool or Rational Application Developer with SCA function. For WebSphere Process Server SCA modules, use a tool such as WebSphere Integration Developer.

### Bindings that support interoperability between Open SCA client services and WebSphere Process Server SCA modules

Currently, four bindings support interoperability between Open SCA client services and WebSphere Process Server SCA modules:

- SCA binding
- EJB binding
- Web service binding
- JMS binding

### SCA binding

When configuring a reference to a WebSphere Process Server SCA module export over SCA binding the following restrictions apply:

- Only synchronous invocations of request-response (two-way) operations are supported.
- All components or modules must be in the same WebSphere Application Server cell definition. The SCA binding is not supported across the cell.
- Both the Open SCA component and the WebSphere Process Server SCA module must use a WSDL interface that meets the following requirements:
  - Web Services Description Language (WSDL) Version 1.1
  - WS-I Basic Profile Version 1.1
  - Simple SOAP Binding Profile 1.0 standards
  - Document literal style

#### Constructing a URI for a WebSphere Process Server SCA module export over SCA binding

WebSphere Process Server SCA module export is exposed using a uniform resource indicator (URI) that is constructed as follows:

*module_name/export_name*

The *module_name* and *export_name* variables are defined in the WebSphere Process Server application. You can view the values from either WebSphere Integration Developer or from the administrative console.

Specify this URI as the reference target URI or as the URI in the `binding.sca` element in the `.composite` file. For example, for a WebSphere Process Server module named `HelloWorldModule` and a WebSphere Process Server export named `/test/sca/ClassicHelloWorld`, the `.composite` file resembles the following:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0" autowire="false"
       name="HelloWorldClientComposite" targetNamespace="http://sca.test">
  <component name="HelloWorldClientComponent">
    <implementation.java class="test.sca.open.OpenHelloWorldClient"/>
    <reference name="classicHWReference" target="HelloWorldModule/test/sca/ClassicHelloWorld">
      <interface.wsdl interface="http://sca.test#wsdl.interface(HelloWorldInterface)"/>
      <binding.sca/>
    </reference>
  </component>
</composite>
```

or:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0" autowire="false"
       name="HelloWorldClientComposite" targetNamespace="http://sca.test">
  <component name="HelloWorldClientComponent">
    <implementation.java class="test.sca.open.OpenHelloWorldClient"/>
    <reference name="classicHWReference">
      <interface.wsdl interface="http://sca.test#wsdl.interface(HelloWorldInterface)"/>
      <binding.sca uri="HelloWorldModule/test/sca/ClassicHelloWorld"//>
    </reference>
  </component>
</composite>
```

### EJB binding

When configuring a reference to a WebSphere Process Server SCA module export over an EJB binding, the following restrictions apply:

- Only synchronous invocations are supported.
- Only EJB 3.x protocol is supported.
- Both the Open SCA component and WebSphere Process Server SCA module must use a Java interface that conforms to the EJB 3.x programming model.

### Web service (JAX-WS) binding

When configuring a reference to a WebSphere Process Server SCA module over a Web service binding, the following features are supported:

- Asynchronous (one-way) and synchronous (request or response) invocations

- The SOAP1.1/HTTP or SOAP1.2/HTTP protocols
- Web Services Atomic Transaction and Web Services Security qualities of service

When configuring a reference to a WebSphere Process Server SCA module over a Web service binding, the following restrictions apply:

- Callback is not supported for non-SCA services like WebSphere Process Server SCA export modules.
- Both the Open SCA component and the WebSphere Process Server SCA module must use a WSDL interface that meets the following requirements:
  - Web Services Description Language (WSDL) Version 1.1
  - WS-I Basic Profile Version 1.1
  - Simple SOAP Binding Profile 1.0 standards
  - Document literal style

**JMS binding**

When configuring a reference to a WebSphere Process Server SCA module over a JMS binding, the following features are supported:

- Asynchronous (one-way) and synchronous (request or response) invocations
- JMS provider platform messaging (JMS binding)
- JMS provider WebSphere MQ (WebSphere MQ JMS binding)

When configuring a reference to a WebSphere Process Server SCA module over a JMS binding, the following restrictions apply:

- When using `commonj.sdo.DataObject` as a parameter type in Java, `wireFormat.jmsObject` is not supported. Although both the SCA and WebSphere Process Server application Java programming models support the use of the same Java-serializable type, `commonj.sdo.DataObject`, and `wireFormat.jmsObject` results in Java serialization, the `commonj.sdo.DataObject` interface is backed by different implementations in each of the two environments. Thus, this wire format is not an interoperable option. Instead, use an XML wire format, such as `wireFormat.jmsTextXML` or `wireFormat.jmsBytesXML`, or use `wireFormat.jmsdefault`.
- Callback is not supported.

### Data types

Business graphs are not interoperable across any SCA bindings and, therefore, are not supported in interfaces used to interoperate with SCA.

## Creating wire format handlers

You can use a wire format handler to transform data between a Service Component Architecture (SCA) application and the application binding.

### Before you begin

This topic assumes that you have an SCA application with a specified binding. The product supports wire format handling for a Java Message Service (JMS) binding.

### About this task

You can implement a wire format handler that converts data between an application wire format and a JMS Message wire format that is used by the JMS destination of a JMS binding.

Creating a wire format handler consists of two main steps:

1. Implement a Java interface that defines the wire format handler.

2. Configure the wire format handler in the composite definition file of the SCA application.

## Procedure

1. Implement the wire format handler interface.

   The wire format handler provides function that transforms one form (source) to another. The result of a transformation is mapped into either object source or JMS message source. The wire format handler must implement the WireFormatHandler interface, which has methods that map into the two source types.

   See the following example wire format handler interface:

```
package com.ibm.websphere.soa.sca.wireformat;

public interface WireFormatHandler {

    /**
  * Transform.
  *
  * @param source
  *            the source
  *
  * @return the object
  *
  * @throws WireFormatHandlerException
  *             the wire format handler exception
  */
    public Object transform(Object source)
        throws WireFormatHandlerException;

    /**
  * Sets the wire format context.
  *
  * @param ctx
  *            the new wire format context
  */
    public void setWireFormatContext(WireFormatContext ctx);

    /**
  * Gets the wire format context.
  *
  * @return the wire format context
  */
    public WireFormatContext getWireFormatContext();}
```

   In the `public Object transform` method implementation, the wire format handler transforms data from the source object to a target object. If an error occurs during the transformation, the data handler implementation throws a WireFormatHandlerException.

   The `public void setWireFormatContext` method implementation sets the runtime context of the wire format handler. The `public WireFormatContext getWireFormatContext` method implementation gets the runtime context of the wire format handler. Even if you do not intend to use the context object, you must implement these methods.

   The wire format context contains runtime contextual information passed from the caller to the wire format handler. The WireFormatContext interface specifies the runtime context of the wire format handler. Each wire format handler implementation must implement the `setWireFormatContext` method of the WireFormatContext interface.

   The WireFormatContext class provides a java.util.Map interface where you can set property key and value pairs in the context. The WireFormatContext interface also provides several methods to extract useful information about the current context such as component and service names, invocation types, and the ability to mark exceptions. Refer to the Java documentation for the com.ibm.websphere.soa.sca.wireformat.WireFormatContext interface for a complete list of methods.

2. Configure the wire format handler in the SCA composite definition file.

   Configuring a wire format handler consists of specifying the configuration properties at authoring time and then accessing the configuration properties at run time. Update the composite definition file of your SCA composite to instruct the component to use the wire format handler class; for example:

```
xmlns:fep="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"

<component name="Account">
  <implementation.java class="helloworld.AccountComponent"/>
  <service name="Account">
    <binding.jms>
      <destination ...>
```

```
      <response>
        ...
      </response>
      <fep:wireFormat.jmsCustom class="helloworld.custom.FirstWFH"/>
    </binding.jms>
  </service>
</component>
```

### What to do next

Deploy your SCA application and test its behavior.

## Wire format handler errors

A wire format handler can transform data between a Service Component Architecture (SCA) application and the application binding. This topic discusses the different types of exceptions and errors that can result at run time in an SCA application that uses wire format handlers. The product supports wire format handling for a Java Message Service (JMS) binding.

- Business exceptions
- Runtime exceptions
- Service and reference exceptions
- Exception handling from a wire format handler

### Business exceptions

Business exceptions are business errors or exceptions that occur during processing.

A business exception is a checked exception. It inherits from the Exception class. Client code must handle a checked exception in a catch clause or with a throws clause.

When a business exception occurs, a checked exception object results from the service business exception in the SCA application. The object calls the wire format handler that is configured on the service.

### Runtime exceptions

Runtime exceptions are exceptions that occur in the SCA application from processing of a request. Runtime exceptions do not correspond to business exceptions. Unlike business exceptions, runtime exceptions are not defined on the interface.

You can propagate runtime exceptions to the client application so that the client application handles the exceptions. For example, if a client sends a request to create a customer to an SCA application and an authorization error occurs during processing of this request, the SCA component throws a runtime exception. This runtime exception must be propagated back to the calling client so it can act on the authorization request. You can use a wire format handler configured on the reference to propagate runtime exceptions back to the calling client application.

### Service and reference exceptions

To handle both business exceptions and runtime exceptions, you can set up exception handling on the application bindings. Handling exceptions on either the reference or service on a binding is optional.

You likely create exception wire format handlers for the most common errors that occur at run time in your application:

- When the exception thrown by the SCA application service must be transformed to a value the client can understand.
- When the incoming exception received on a reference must be transformed to a value the client code can understand.

## Exception handling from a wire format handler

An exception handler is a wire format handler. Business and runtime exception handling is done from the wire format handler An exception wire format handler transforms specific exceptions into objects that can be understood by the client application.

Both service and reference bindings can use an exception wire format handler. You can configure an exception wire format handler to do the following:

- Handle runtime exceptions that are received from external applications (reference)
- Send runtime exceptions that have occurred in your SCA application to the external applications (service)

On the service implementation of a wire format handler, the implementation can examine the WireFormatContext.INVOCATION value from the context to find that an exception was thrown. The wire format handler might handle normal invocations and exceptions differently. See the following sample code:

```
public Message transformIntoJMSMessage(Session session, Object source)
   throws JMSException, WireFormatHandlerException {

   WireFormatContext.INVOCATION invocationType =
      (WireFormatContext.INVOCATION) context.get(WireFormatContext.INVOCATION_TYPE);

   if (invocationType == WireFormatContext.INVOCATION.TYPE_EXCEPTION) {
      return handleException(session, source);
   } else if (invocationType == WireFormatContext.INVOCATION.TYPE_RESPONSE) {
      return handleResponse(session, source);
   } else {
      throw new WireFormatHandlerException("Unexpected Invocation Type.");
   }
}
```

On the reference implementation of a wire format handler, the implementation must determine at run time if the incoming response is of type fault. The WireFormatContext.INVOCATION value must be initially set to TYPE_RESPONSE. The implementation examines incoming messages. When an incoming message is an exception rather than a normal response, the implementation must set the invocation type to TYPE_EXCEPTION and throw an appropriate exception. See the following code sample:

```
// On Reference-side, this is for an incoming response
public Object transformFromJMSMessage(Message source)
  throws WireFormatHandlerException {

  ObjectMessage msg = null;
  Object payload = null;
  Object[] payloadArray = null;
  Integer payloadInt = null;
  Object payloadItem = null;

  try {
    msg = (ObjectMessage)source;
  } catch (ClassCastException cce) {
      throw new WireFormatHandlerException("Did not receive ObjectMessage", cce);
  }
  try {
    payload = msg.getObject();
  } catch (JMSException e) {
      throw new WireFormatHandlerException("Cannot get Object from message using getObject()", e);
  }

  if (payload instanceof Integer) {
    // Expected type returned
    payloadInt  = (Integer)payload;
    Integer code = new Integer(0);
    Integer one = new Integer(1);
    code = payloadInt + one;
```

```
    return code;
  } else {
    // Response is some type of exception...

    // Change the response type to Exception
    context.put(WireFormatContext.INVOCATION_TYPE, WireFormatContext.INVOCATION.TYPE_EXCEPTION);

    if (payload instanceof Throwable) {
      Throwable thw = (Throwable) payload;

      ////////////////////////////////////////////////////
      // TO DO: Map to checked business exception and throw it
      ////////////////////////////////////////////////////

    } else {
      return new ServiceRuntimeException(((Throwable) payload).getMessage());
      // Unchecked
    }
  } else {
    throw new WireFormatHandlerException("Unexpected Object returned: " + payload);
    // Unexpected or unknown object returned.
    }
  }
}
```

# Using existing Java EE modules and components as SCA implementations

You can use the Service Component Architecture (SCA) programming model to invoke business services in Java Platform, Enterprise Edition (Java EE) components.

## About this task

The SCA programming model supports Java EE integration. You can expose Enterprise JavaBeans (EJB) stateless session beans as SCA services. You can take advantage of SCA annotations to enable the Java EE components, such as session beans, message driven beans, or web components to consume SCA services. You also can rewire EJB references to SCA services. Thus, you can enable an existing Java EE component so that it is recognized as an SCA component and so that the component can participate in an SCA composite.

## Procedure

1. Use non-SCA enhanced Java EE applications as SCA component implementations.
2. Use SCA enhanced Java EE applications as SCA component implementations.

   For this step, create an `application.composite` file. Then, determine the Java EE component type that you want to consume SCA services. Depending on the Java EE component type, use SCA annotations:

   - Use SCA annotations with web modules.
   - Use SCA annotations with session beans.
   - Use SCA annotations with message-driven beans.

   If your application uses security, specify security roles and runAs identity in the Java EE application implementation instead of in the composite. Authorization policy is enforced by the implementation.
3. Rewire EJB references to SCA references.
4. Deploy an SCA composite using a Java EE application as a component implementation.

   You can deploy an SCA composite that uses an `implementation.jee` defining a Java EE application as a component implementation. Deploy the SCA composite that uses the application as a component implementation along with the enterprise archive (EAR) file. Add the SCA composite and Java EE application as composition units of a business-level application.

a. Import the EAR file as an asset.
b. Import the SCA composite Java archive (JAR) file as an asset.
c. Create an empty business-level application.
d. Add the EAR file asset to the business-level application.
e. Add the SCA composite asset to the business-level application. Map the SCA composite to the same target server as the EAR file.
f. If you are rewiring EJB references, set the starting weight of the EAR file to a greater value than the starting weight of the SCA composite. The SCA composite then starts before the EAR file.

When deploying an SCA JAR contribution that has a deployable SCA composite with `implementation.jee` for one or more of its SCA components, ensure that the following requirements are met:

- Deploy the SCA deployable composite and all the Java EE applications used for the SCA component implementation in the same business-level application.
- Add all the Java EE applications referenced by the `archive` attribute of the `implementation.jee` directive to the business-level application before adding the SCA deployable composite.
- Map all the deployed components of an SCA business-level application to the same target server or cluster.
- When using an SCA enhanced EAR file that requires injection of values for SCA references, properties, context or component names in Java EE modules such as stateless session beans, servlets, or JSP files, the deployed SCA asset must start before the Java EE asset. If necessary, set the weights of the composition units so that the deployed SCA asset starts before the Java EE asset.
- If you update Java EE composition units, deploy the SCA composition unit again to apply the changes in the SCA component that uses Java EE implementation.

5. Start the business-level application.

## Results

You now have defined and deployed Java EE components to take advantage of the SCA programming model. The SCA composite and the EAR file are deployed and started, and the Java EE application is able to participate in the SCA domain.

Invoke the EJB services exposed as SCA services using the SCA programming model.

## Example

The product provides the HelloJee sample to show how to use SCA annotations within Java EE components so that these components can consume SCA services.

This sample uses the `HelloJeeEar.ear`, `HelloJeeEnhancedEar.ear`, and `HelloJeeSca.jar` SCA sample files. To download HelloJee sample files from a product website:

1. Go to the **Samples, Version 8.0** information center.
2. On the **Downloads** tab, click **FTP** or **HTTP** in the **Service Component Architecture** section.
3. In the authentication window, click **OK**.
4. From the **SCA.zip** compressed file, download prebuilt `HelloJeeEar.ear`, `HelloJeeEnhancedEar.ear`, and `HelloJeeSca.jar` files in the `SCA/installableApps` directory.

   If you want to build your own deployable files, download the `SCA/HelloJee` directory and follow instructions in `SCA/HelloJee/documentation/readme.html` to build the files.

Briefly, to deploy the HelloJee sample, do the following:

1. Import as assets the `HelloJeeEar.ear`, `HelloJeeEnhancedEar.ear`, and `HelloJeeSca.jar` files.

2. Create a business-level application named `HelloJeeBla`.
3. Add the `HelloJeeEar.ear` and `HelloJeeEnhancedEar.ear` assets to the business-level application.
4. Add the `HelloJeeSca.jar` asset to the business-level application. When adding the asset, ensure that it is targeted to the same server or node as the EAR files added in step 3. If you are adding the JAR file using the administrative console, ensure that components HelloJeeEnhancedComponent and HelloJeeComponent are listed on the Set Java EE composition unit relationships page. Also ensure that HelloJeeEnhancedComponent associates with the HelloJeeEnhancedEar composition unit and HelloJeeComponent associates with the HelloJeeEar composition unit.
5. Start the business-level application.
6. Run the sample application. Open a web browser on a URL that accesses a sample. The following URLs use `localhost` for host name and `9080` for port number. Use the host name and `WC_defaulthost` port number that is correct for your installation.
   - Access the non-SCA enhanced EJB as is: `http://localhost:9080/HelloJeeWeb/JeeEjbClient`
   - Access the non-SCA enhanced EJB as an SCA service: `http://localhost:9080/HelloJeeWeb/JeeScaClient`
   - Access the SCA enhanced EJB as is: `http://localhost:9080/HelloJeeEnhancedWeb/JeeEEjbClient`
   - Access the SCA enhanced EJB service or reference as an SCA service or reference and demonstrate SCA annotations: `http://localhost:9080/HelloJeeEnhancedWeb/JeeEScaClient`

# Using non-SCA enhanced Java EE applications as SCA component implementations

You can use an existing Java Platform, Enterprise Edition (Java EE) application as a Service Component Architecture (SCA) component without requiring SCA annotations or composite files.

## Before you begin

Identify the Java EE application that contains business logic in Enterprise JavaBeans (EJB) or web modules to enable in the SCA environment.

A Java EE application is also called an enterprise application or enterprise archive (EAR) file.

## About this task

The SCA programming model supports Java EE integration. You can expose EJB stateless session beans as SCA services by enabling an existing enterprise application module to be recognized as an SCA component and participate in an SCA composite.

You can use an enterprise application as an SCA component implementation, without requiring any SCA annotations or composite files in the application. Such an application is denoted as a non-SCA enhanced enterprise application.

The EJB business interfaces of stateless session beans configured in EJB modules are exposed as SCA services. The EJB business interfaces of EJB references configured in EJB and web modules are exposed as SCA references.

The component type of a non-SCA enhanced enterprise application is defined as follows:

- Each EJB 3.x session bean business interface with unqualified name `intf` of a session bean with mapped name `mname` translates into a service by the name `mname_intf`.
- The service interface that is derived from the business interface of an EJB 3.x session bean consists of all methods of the EJB business interface.
- The service interface is remotable if it is derived from a remote business interface. Each EJB 3.x remote reference of each session bean within the enterprise application is exposed as an SCA reference. If the

remote reference has the name ref and the name of the session bean is beanname, the SCA reference name is beanname_ref. Services thus derived can be invoked or wired to like an SCA service.

## Procedure

1. Create a component in an SCA composite definition. Specify the implementation.jee component type and set the archive attribute to the name of the asset object.

   For example, the composite definition for a implementation.jee component named ImplJeeComponent that uses the MyJEE.ear archive resembles the following:

   ```
   <?xml version="1.0" encoding="UTF-8"?>
   <composite xmlns="http://www.osoa.org/xmlns/sca/1.0"; autowire="false"
       name="ImplJeeSCAComposite"
       targetNamespace="' class='inlinelink' target="_blank">http://jee">
     <component name="ImplJeeComponent">
       <implementation.jee archive="MyJEE.ear"/>
     </component>
   </composite>
   ```

2. Optional: Write client code that looks up and invokes a derived SCA service.

   A client can look up and invoke a derived SCA service. For example, suppose the ImplJeeComponent component has a stateless session bean named Bean1 with a remote interface Intf1 in an EJB module in the enterprise application. Invoke the service with code such as the following:

   ```
   CompositeContext compositeContext = CurrentCompositeContext.getContext();
   Intf1 myEjb = compositeContext.getService(Intf1.class, "ImplJeeComponent/Bean1_Intf1");
   retStr = ejb.myOperation();
   ```

3. Optional: Define a reference to a derived service in an SCA component composite. Use the injected value of a matching @Reference SCA annotation to invoke an EJB service as an SCA service.

   Instead of writing client code to look up and invoke the derived SCA server (step 2), you can define a reference to the derived service in an SCA component composite. An SCA service in a component can use the injected value of a matching @Reference SCA annotation to invoke the EJB service as a SCA service.

   For example, the ImplJeeComponent component might invoke an EJB service as a SCA service using the following code. The SCA component reference code resembles:

   ```
   <reference name="MyRef" target="ImplJeeComponent/Bean1_Intf1>
   ```

   The SCA service code resembles:

   ```
   @Reference public Intf1 MyRef;
   .....
   String retStr = MyRef.myOperation();
   ....
   ```

## Results

The enterprise application is available as an SCA component type. Any SCA component can refer to the derived services.

## What to do next

Deploy the enterprise application and the SCA composite that uses the application as composition units of the same business-level application. You can use the administrative console or wsadmin commands to create the business-level application and add the enterprise application and the SCA composite as composition units.

The product provides the HelloJee sample. The sample has a non-SCA enhanced EJB. The Example section in the Using existing Java EE modules and components as SCA implementations topic summarizes how to deploy the HelloJee sample and access the non-SCA enhanced EJB.

# Using SCA enhanced Java EE applications as SCA component implementations

You can use an existing Java Platform, Enterprise Edition (Java EE) application as a Service Component Architecture (SCA) component after enhancing the application. Define an SCA composite that has components with `implementation.ejb` and `implementation.web` component types which refer to Enterprise JavaBeans (EJB) and web modules within the Java EE application, and then promote services and references.

## Before you begin

Identify the Java EE application that contains business logic in EJB or web modules to enable in the SCA environment.

A Java EE application is also called an enterprise application or enterprise archive (EAR) file.

## About this task

The SCA programming model supports Java EE integration. You can expose EJB stateless session beans as SCA services by enabling an existing enterprise application module to be recognized as an SCA component and participate in an SCA composite. You can rewire the SCA services over different bindings. You can rewire EJB references in EJB and web modules to SCA references. Also, you can use SCA annotations to enable Java EE components such as stateless session beans, message driven beans, servlets, listeners, filters, and JavaServer Pages (JSP) files to consume SCA services and properties.

Define a composite in a file named `application.composite` and place the file in the enterprise application `META-INF` directory.

## Procedure

1. Create a file named `application.composite` that defines components with component types of web and EJB modules of the enterprise application. Save the file to the enterprise application `META-INF` directory.

   Use the `implementation.web` element to declare a service component that is implemented by the web component. The component contains information for the annotations. To configure a web component implementation, use the following schema:

```
<implementation.web web-uri="web_module_name"/>
```

   Use the `implementation.ejb` element to declare a service component that is implemented by a session bean component. To configure an EJB component implementation, use the following schema:

```
<implementation.ejb ejb-link="EJB_module_name"/>
```

   The components can contain one or more supported elements, such as `<service>`, `<reference>`, and `<property>` elements. In the composite definition, promote the services and references to be available in the SCA component using the enterprise application as the component type.

   An example `application.composite` file for an enterprise application named `MyEAR.ear` follows. The file contains an EJB module named `myEJB.jar` with a bean named `MyBean` and a remote business interface named `MyRemoteIntf`. The file also contains a Web module named `myWeb.war`.

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"; autowire="false" name="MyComposite"
        targetNamespace="' class='inlinelink' target="_blank">http://jee">

  <service name="MyBean_MyRemoteIntf" promote="MyEJBComponent/MyBean_MyRemoteIntf"/>
  <reference name="MySCAReference1" promote="MyEJBComponent/MySCAReference1"/>
  <reference name="MySCAReference2" promote="MyWebComponent/MySCAReference2"/>

  <component name="MyEJBComponent">
    <implementation.ejb ejb-link="MyEJB.jar#MyBean"/>
    <service name="MyBean_MyRemoteIntf">
      <interface.java ... />
    </service>
    <reference name="MySCAReference1" target="MySCAComponent1">
  </component>
```

```
  <component name="MyWebComponent">
    <implementation.web web-uri="MyWeb.war"/>
    <reference name="MySCAReference2" target="MySCAComponent2">
  </component>
</composite>
```

2. Create a component in an SCA composite definition that has the `implementation.jee` component type and the `archive` attribute set to the name of the enterprise application asset object.

   For the example enterprise application `MyEAR.ear`, create a component such as the following:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite xmlns="http://www.osoa.org/xmlns/sca/1.0"; autowire="false" name="ImplJeeSCAComposite"
      targetNamespace="' class='inlinelink' target="_blank">http://jee">
  <component name="ImplJeeComponent">
    <implementation.jee archive="MyEAR.ear"/>
  </component>
</composite>
```

3. Inject the promoted references into @Reference annotations in the EJB and web modules. Also, rewire the promoted service, and reference the service from other SCA components.

   For information about using a composite file to support annotations, refer to the following topics:
   - Using SCA annotations with web modules
   - Using SCA annotations with session beans
   - Using SCA annotations with message-driven beans

4. Using a client or an SCA service, invoke the promoted EJB as an SCA service.

## Results

The enterprise application is available as an SCA component type. Any SCA component can refer to the promoted services. Java EE modules can access SCA services and properties using SCA annotations. You can rewire the services and reference them like any other SCA service.

## What to do next

Deploy the enterprise application and the SCA composite that uses the application as composition units of the same business-level application. You can use the administrative console or wsadmin commands to create the business-level application and add the enterprise application and the SCA composite as composition units.

The product provides the HelloJee sample. The sample has an SCA enhanced EJB. The Example section in the Using existing Java EE modules and components as SCA implementations topic summarizes how to deploy the HelloJee sample and access the SCA enhanced EJB.

## Using SCA annotations with web modules

Use Java annotations for Service Component Architecture (SCA) to identify existing Java Platform, Enterprise Edition (Java EE) components, such as web modules, as SCA components that are a part of an SCA composite.

### Before you begin

Identify and obtain the web module that represents your business logic that you want to enable within an SCA environment.

### About this task

The SCA programming model supports Java EE integration. As a result, you can take advantage of SCA annotations to enable Java EE web components such as servlets, filters, and event listeners to consume SCA services. By using Java annotations that apply to SCA, you can enable existing web modules to be recognized as an SCA component and participate in an SCA composite.

Web modules can participate in SCA assembly as the implementation type of a component that does not offer services, even though you can configure or wire the component to other services. You can configure

a web module with annotations to acquire references to services that are wired to the component by the SCA assembly. You can also use annotations when you want to obtain the value of a property using the @Property annotation, to inject a handle to the SCA component context using the @Context annotation or to obtain the component name using the @ComponentName annotation.

For a list of supported annotations for web modules, see the SCA specifications and APIs documentation.

You can also obtain SCA references in JavaServer Pages (JSP) files by using SCA JSP tag libraries. The following example illustrates how annotations are used within a JSP tag handler:

```
<%@ taglib uri="http://www.osoa.org/sca/sca_jsp.tld" prefix="sca" %>
<sca:reference name="service" type="test.MyService"  />
<% service.sayHello(); %>
```

## Procedure

1. Add SCA annotations to the components that you want within a web module. Based on your needs, use the supported annotations to inject SCA information into your web module.
2. Define a component in the `application.composite` file in the `META-INF` directory.

   The `implementation.web` element is used to declare a service component that is implemented by the web component. The component contains information for the annotations. To configure this component implementation, use the following schema:

   ```
   <implementation.web web-uri="<module name>"/>
   ```

   For example, you can define a component in the EAR `META-INF/application.composite` file as follows:

```
<component name="WebAnnotationTestServletComponent">
   <implementation.web web-uri="SCA_JEE_InjectionWeb.war"/>
   <reference name="getServerDateReference" target="GetServerDateServiceComponent">
       <interface.java interface="sca.injection.test.GetServerDateService"/>
   </reference>
</component>
```

   The following example illustrates a servlet in the web application archive (WAR) module using SCA annotations:

```
 public class WebAnnotationTestServlet extends HttpServlet {
     @Reference GetServerDateService getServerDateReference;
 }
```

   The following example illustrates a JSP using SCA annotations by importing the SCA tag library:

```
<%@ page language="java" contentType="text/html; charset=ISO-8859-1"
pageEncoding="ISO-8859-1"%>
<%@ taglib uri="http://www.osoa.org/sca/sca_jsp.tld" prefix="sca" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD HTML 4.01 Transitional//EN
" "http://www.w3.org/TR/html4/loose.dtd">

<sca:reference name="getServerDateReference"
type="sca.injection.test.GetServerDateService" />
<html>
   <head>
    <meta http-equiv="Content-Type" content="text/html; charset=ISO-8859-1">
    <title>TESTING SCA ANNOTATION IN JSP</title>
   </head>
   <body>
   <h2> Reference Annotation in JSP: </h2>
     GetServerDateService.getString returns : <%=getServerDateReference.getString() %>
   </body>
</html>
```

## Results

You now have SCA-enabled Java EE web modules that take advantage of the SCA programming model.

## What to do next

Deploy the components to a business-level application.

## Using SCA annotations with session beans

Use Java annotations for Service Component Architecture (SCA) to identify existing Java Platform, Enterprise Edition (Java EE) components, such as session beans, as SCA components that are a part of an SCA composite.

### Before you begin

Identify and obtain the session beans that represent your business logic that you want to enable within an SCA environment.

### About this task

The SCA programming model supports Java EE integration. As a result, you can take advantage of SCA annotations to enable Java EE web components such as session beans to consume SCA services. By using Java annotations that apply to SCA, you can enable existing session beans to be recognized as an SCA component and participate in an SCA composite. Within Java EE environments, sessions beans encapsulate business logic to manage security, transactions, and remotable interfaces. Because service components within SCA environments play a similar role, you can take advantage of the capability to use session beans as a service component implementation in a Java EE environment.

Any session bean that serves as the implementation type of an SCA service component can use annotations to obtain an interface to the SCA services that are wired to the component by the SCA assembly. You can also use annotations when you want to obtain the value of a property using the @Property annotation, to inject a handle to the SCA component context using the @Context annotation or to obtain the component name using the @ComponentName annotation. When using SCA annotations, you must apply the injection using annotations after the session bean instance is created, but before invoking business methods on the bean instance.

For a list of supported annotations for session beans, see the SCA specifications and APIs documentation.

### Procedure

1. Add SCA annotations to the components that you want within your session beans to enable the component to be recognized as an SCA component. Based on your needs, use the supported annotations to inject SCA information such as context or component name into your session beans.
2. Edit the `application.composite` in the `META-INF` directory of the Java EE JAR file.

   Define a component within the `application.composite` file whose implementation is defined by an `implementation.ejb` element and specifies a session bean within the module. You can define multiple components, each with an `implementation.ejb` link that points to a session bean.

   Because message-driven beans and session beans are enterprise beans, you can uniquely refer to both bean types in an ejb-link element.

   The `implementation.ejb` element is used to declare a service component that is implemented by the session bean component. The component contains information for the annotations. To configure this component implementation, use the following schema:

   ```
   <implementation.ejb ejb-link="<ejb_link_name>"/>
   ```

   The enterprise bean that serves as the component implementation is uniquely identified by the *<ejb_link_name>* attribute. The format of the *<ejb_link_name>* attribute is identical to the format of the ejb-link element in a Java EE deployment descriptor.

   If the Java EE archive that contains the composite file is an application enterprise archive (EAR) file, multiple session beans might have the same name. In this case, the value of the ejb-link element must be composed of a path name. The path name specifies the ejb-jar that contains the referenced enterprise bean with the value of the ejb-name of the referenced enterprise bean appended and separated from the path name with the `#` symbol. The path name is relative to the root of the EAR file. For the case where the Java EE archive is a JAR file for the Enterprise JavaBeans (EJB) module, omit the path name.

For example, you can have a JAR module that has the following component defined in the `application.composite` file:

```
<component name="AnnotationTest">
    <implementation.ejb ejb-link="SCA_JEE_Injection.jar#AnnotationTest"/>
        <property name="property" type="xsd:string">Right</property>

    <reference name="getServerDateReference" target="GetServerDateServiceComponent">
    <interface.java interface="sca.injection.test.GetServerDateService"/>
    </reference>

</component>
```

In this example, the session bean, AnnotationTest, is consuming an SCA service exposed by the GetServerDataServiceComponent reference.

The AnnotationTest session bean includes the @Property, @Reference, @ComponentName, and @Context annotations:

```
import javax.ejb.Stateless;

import org.osoa.sca.ComponentContext;
import org.osoa.sca.annotations.ComponentName;
import org.osoa.sca.annotations.Context;
import org.osoa.sca.annotations.Property;
import org.osoa.sca.annotations.Reference;

import sca.injection.test.GetServerDateService;
/**
* Session Bean implementation class AnnotationTest
*/
@Stateless
public class AnnotationTest implements AnnotationTestRemote, AnnotationTestLocal {

@Context protected ComponentContext myContext;
@ComponentName String myCompName;
@Property protected String property;
@Reference GetServerDateService getServerDateReference;

@Reference
GetServerDateService referenceDefault;

/**
* Default constructor.
*/
public AnnotationTest() {
// TODO Auto-generated constructor stub
}

public String getServString(){
GetServerDateService svc = myContext.getService(GetServerDateService.class, "getServerDateReference");
return svc.getString();
}

public String getProperty(){
return property;
}
public String getComponentName(){
return myCompName;
}
public String getReferenceDefault() {
if ( referenceDefault == null )
return null;
else
return referenceDefault.getString();
}

}
```

### Results

You now have SCA-enabled Java EE session beans that take advantage of the SCA programming model.

### What to do next

Deploy the components to a business-level application.

## Using SCA annotations with message-driven beans

Use Java annotations for Service Component Architecture (SCA) to identify existing Java Platform, Enterprise Edition (Java EE) components, such as message-driven beans, as SCA components that are a part of an SCA composite.

### Before you begin

Identify and obtain the message-driven beans that represent your business logic that you want to enable within an SCA environment.

### About this task

The SCA programming model supports Java EE integration. As a result, you can take advantage of SCA annotations to enable Java EE web components such as message-driven beans to consume SCA services. By using Java annotations that apply to SCA, you can enable existing message-driven beans to be recognized as an SCA component and participate in an SCA composite.

Message-driven beans can only participate in SCA assembly as the implementation type of a component that does not offer services, even though you can configure or wire the component to other services. Because of the association with endpoints that are not controlled by SCA such as Java Message Service (JMS), do not instantiate message-driven beans arbitrarily. You must not use a message-driven bean as a service component implementation more than one time within the SCA assembly of the application package.

You can configure a message-driven bean that is defined as an implementation type of an SCA component with annotations in order to obtain references to services that are wired to the component by the SCA assembly by using the @Reference annotation. You can also use annotations when you want to obtain the value of a property using the @Property annotation, to inject a handle to the SCA component context using the @Context annotation or to obtain the component name using the @ComponentName annotation.

For a list of supported annotations for message-driven beans, see the SCA specifications and APIs documentation.

### Procedure

1. Add SCA annotations to the components that you want within your message-driven beans. Based on your needs, use the supported annotations to inject SCA information into your message-driven beans.
2. Edit the `application.composite` in the META-INF directory of the Java EE JAR file.

   Define a component within the `application.composite` whose implementation is defined by an `implementation.ejb` element and specifies a message-driven bean within the module. You can define multiple components, each with an `implementation.ejb` link that points to a message-driven bean.

   Because message-driven beans and session beans are enterprise beans, you can uniquely refer to both bean types in an ejb-link element.

   The `implementation.ejb` element is used to declare a service component that is implemented by the message-driven bean component. The component contains information for the annotations. To configure this component implementation, use the following schema:

   ```
   <implementation.ejb ejb-link="<ejb_link_name>"/>
   ```

The enterprise bean that serves as the component implementation is uniquely identified by the *<ejb_link_name>* attribute. The format of the *<ejb_link_name>* attribute is identical to the format of the ejb-link element in a Java EE deployment descriptor.

If the Java EE archive that contains the composite file is an application enterprise archive (EAR) file, it is possible that multiple message-driven beans have the same name. In this case, the value of the ejb-link element must be composed of a path name specifying the ejb-jar that contains the referenced enterprise bean with the ejb-name of the referenced enterprise bean appended and separated from the path name with the # symbol. The path name is relative to the root of the EAR file. For the case where the Java EE archive is a JAR file for the Enterprise JavaBeans (EJB) module, omit the path name.

For example, you can have a JAR module that has the following component defined in the `application.composite`:

```
<component name="AnnotationTest">
     <implementation.ejb ejb-link="SCA_JEE_Injection.jar#AnnotationTest"/>
                <property name="property" type="xsd:string">Right</property>

      <reference name="getServerDateReference" target="GetServerDateServiceComponent">
     <interface.java interface="sca.injection.test.GetServerDateService"/>
      </reference>

</component>
```

In the following example, the message-driven bean, AnnotationTestMDB, is consuming an SCA service exposed by the GetServerDataServiceComponent reference. The AnnotationTestMDB message driven bean includes the @Property and @Reference annotations.

```
@MessageDriven
public class AnnotationTestMDB implements MessageListener {

//Property Annotations
@Property protected String property;

//Reference Annotation
@Reference protected GetServerDateService getServerDateReference;

/**
* Default constructor.
*/
public AnnotationTestMDB() {
// TODO Auto-generated constructor stub
}

private static final String JMSCF_JNDI_NAME = "jms/AnnotationQueueFactory";
private static final String JMSResponseQ_JNDI_NAME = "jms/AnnotationResponseQueue";
/**
* @see MessageListener#onMessage(Message)
*/
public void onMessage(Message message) {
String strDefaultReference = null;

System.out.println("Inside onMessage()");
try {
System.out.println("onMessage: " + "Exercising annotations");
if ( getServerDateReference != null)
strDefaultReference = getServerDateReference.getString();
}
catch (RuntimeException e) {
strError = "Error - Failed WebAnnotationTestServlet.service()!";
e.printStackTrace();
}

if (strError != null){
System.out.println("onMessage: " + "Encountered an error while annotation work");
outSB.append("@FINALERROR" + strError);
} else {
System.out.println("onMessage: " + "Annotations successful: now creating reply message");
outSB.append("@PropertyDefault:" + propertyDefault);
outSB.append("@ReferenceDefault:" + strDefaultReference);
}
}
}
```

### Results

You now have SCA-enabled Java EE message-driven beans to take advantage of the SCA programming model.

### What to do next

Deploy the components to a business-level application.

## SCA annotations

By using Java annotations that apply to Service Component Architecture (SCA), you can enable an existing Java Platform, Enterprise Edition (Java EE) component to be recognized as an SCA component and participate in an SCA composite.

The SCA programming model supports Java EE integration. As a result, you can take advantage of SCA annotations to enable the Java EE components, such as session beans, message driven beans, or web components to consume SCA services.

The target for annotations applies for these Java objects:

- Types such as a Java class, enum or interface
- Methods
- Fields representing local instance variables within a Java class
- Parameters within a Java method

Annotations supported by SCA are listed in the following table:

*Table 138. SCA annotations. The annotations enable Java EE components.*

| Annotation class | Annotation | Properties |
|---|---|---|
| `org.osoa.sca.annotations.ComponentName.class` | The **@ComponentName** annotation specifies the injection of a component name. | • Annotation target: Method or field<br>• There are no properties on the @ComponentName annotation. |
| `org.osoa.sca.annotations.Context.class` | The **@Context** annotation specifies to inject SCA context into a service component instance.<br><br>When you inject a composite context for the component, the type of context is defined by the type of the Java class field or type of the setter method input argument. Specify the type as either ComponentContext or RequestContext. | • Annotation target: Method or field<br>• There are no properties on the @Context annotation. |
| `org.osoa.sca.annotations.Property.class` | The **@Property** annotation specifies to inject configuration properties from service component configuration.<br><br>You can inject a simple Java type or a complex Java type. The type of the property injected is defined by the type of the Java class field or type of the setter method input argument.<br><br>You can use this annotation on protected or public fields, on setter methods, or on a constructor method. | • Annotation target: Method or field<br>• Properties:<br>**- name**<br>The name of the property. The default is the name of the field of the Java class. This property is optional. (String)<br>**- required**<br>Specifies whether injection is required. The default value is `false`. This property is optional. (Boolean) |

*Table 138. SCA annotations (continued). The annotations enable Java EE components.*

| Annotation class | Annotation | Properties |
|---|---|---|
| `org.osoa.sca.annotations.Reference.class` | The **@Reference** annotation specifies the injection of a service reference.<br><br>The interface of the service injected is defined by the type of the Java class field or the type of the setter method input parameter. | • Annotation target: Method or field<br>• Properties:<br>**- name**<br>The name of the property. The default is the name of the field of the Java class. This property is optional. (String)<br>**- required**<br>Specifies whether injection is required. The default value is `false`. This property is optional. (Boolean) |

# Rewiring EJB references to SCA references

You can rewire an Enterprise JavaBeans (EJB) reference to a Service Component Architecture (SCA) reference that provides the same named operations. The rewiring does not require a change to existing code.

## Before you begin

Identify the Java Platform, Enterprise Edition (Java EE) application that contains business logic in EJB or web modules to enable in the SCA environment. A Java EE application is also called an enterprise application or enterprise archive (EAR) file.

Identify the SCA components and services to replace the EJB references in EJB and web modules.

## About this task

The SCA programming model supports Java EE integration. You can rewire EJB references to SCA references without changing existing code that uses the EJB reference. Thus, you can use the SCA programming model without changing the implementation code.

## Procedure

1. Create a file named `application.composite` that defines components with component types of web and EJB modules of the enterprise application. Save the file to the enterprise application `META-INF` directory.

   Use the `implementation.web` element to declare a service component that is implemented by the web component. The component contains information for the annotations. To configure a web component implementation, use the following schema:

```
<implementation.web web-uri="web_module_name"/>
```

   Use the `implementation.ejb` element to declare a service component that is implemented by a session bean component. To configure an EJB component implementation, use the following schema:

```
<implementation.ejb ejb-link="EJB_module_name"/>
```

   To rewire an EJB reference to an SCA service in an SCA component, add a `<reference>` element to the `jee` module component. For example, to rewire an EJB reference named `MyEJBRef` to an SCA service named `MySCASvc` in an SCA component named `MyComponent`, the `<reference>` element resembles the following:

```
<reference name="MyEJBRef" target="MyComponent/MySCASvc">
  <interface.java .... />
</reference>
```

   The reference names must match the name of the EJB reference. The contract of operations supported must also match. Because references must be promoted in the composite, the names of the references must be unique. After the EJB reference is promoted, all matching instances of the EJB reference in the module are rewired to the SCA service.

2. Create a component in an SCA composite definition that has the `implementation.jee` component type and the `archive` attribute set to the name of the enterprise application asset object.

   For an enterprise application named `MyEAR.ear`, create a component such as the following:

```
<component name="ImplJeeComponent">
  <implementation.jee archive="MyEAR.ear"/>
</component>
```

### Results

The EJB references are rewired to SCA references enabling Java EE modules to use SCA features without changing its implementation.

### What to do next

Deploy the enterprise application and the SCA composite that uses the application as composition units of the same business-level application. You can use the administrative console or wsadmin commands to create the business-level application and add the enterprise application and the SCA composite as composition units.

## Using OSGi applications as SCA component implementations

You can use an OSGi application as a Service Component Architecture (SCA) component.

### Before you begin

Identify the OSGi application to use as an SCA component. An OSGi application is a collection of OSGi bundles that use the Blueprint component model to expose or consume services. An OSGi application contains an application manifest that declares the following services:

- Services that the application provides that can be accessed from outside the application
- Services that the application wants to consume from outside the application

You can use SCA to provide service bindings for these services.

### About this task

To provide service bindings using SCA, do the following:

1. Modify an OSGi application to provide or use remote services.
2. Write an SCA composite definition that uses an OSGi application as a component implementation, and provide bindings for its remote services.

An OSGi application declares external services in the Application-ImportService and Application-ExportService statements of its application manifest, which is provided in the `META-INF/APPLICATION.MF` file of the enterprise bundle archive (EBA). The Application-ExportService statement declares remote services that are provided by the OSGi application. The Application-ImportService statement declares services on which the OSGi application depends. All services specified in the application manifest are remotable.

### Procedure

1. Create an `implementation.osgiapp` component in an SCA composite definition.

   Specify the `implementation.osgiapp` component type and set `applicationSymbolicName` and `applicationVersion` to values that match the `Application-SymbolicName` and `Application-Version` attributes in the application manifest.

   For example, suppose the OSGi application manifest, the `META-INF/APPLICATION.MF` file, contains the following headers:

```
Application-SymbolicName: helloworldApp
Application-Version: 1.0.0
```

Configure a component that references these headers in an SCA composite definition; for example:

```
<?xml version="1.0" encoding="UTF-8"?>
<composite
  xmlns="http://www.osoa.org/xmlns/sca/1.0"
  xmlns:scafp="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
  targetNamespace="http://www.example.com"
  name="HelloWorldComposite">
    <component name="HelloWorldComponent">
        <scafp:implementation.osgiapp
           applicationSymbolicName="helloworldApp"
           applicationVersion="1.0.0"/>
    </component></composite>
```

The `implementation.osgiapp` element requires the use of an XML namespace prefix that is associated with the `"http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"` namespace.

The `applicationVersion` attribute is optional. You can add it to ensure that a particular version of an OSGi application is used.

2. Identify Blueprint services to be made available remotely.
   a. Edit the Application-ExportService header in the OSGi application manifest so that it identifies one or more service interfaces to be exported.

      The following example header specifies that Blueprint services which implement and export the `example.HelloWorld` interface are to be made available outside the application.

      ```
      Application-ExportService: example.HelloWorld
      ```

      An example of a Blueprint component with such a service follows:

      ```
      <blueprint xmlns="http://www.osgi.org/xmlns/blueprint/v1.0.0">
      <bean id="helloWorldComponent" class="example.HelloWorldImpl"
        <service id="helloWorld" ref="helloWorldComponent"
           interface="example.HelloWorld">
         <service-properties>
           <entry key="service.exported.interfaces" value="*"/>
         </service-properties>
        </service>
      </blueprint>
      ```

      The Blueprint service must specify the `service.exported.interfaces` property to identify which of its interfaces are to be exposed remotely. The value can be an asterisk (`*`) to indicate that all of its interfaces are available remotely, or it can be a particular interface name.

   b. Configure an SCA service that corresponds to each remotable Blueprint service in the component.

      Use the Blueprint service `id` value for the SCA service name. If a Blueprint service does not have an `id` value, use the bean `id` value instead. If more than one interface is defined for the Blueprint service, for the first service interface SCA Service name use the Blueprint `id` value. For the second and later services, use the *`Blueprint id_ fully qualified interface name`* value for the SCA service name in the order of interfaces defined in the `blueprint.xml` file.

      For example, add the `helloWorld` service that is shown in the Blueprint component from step 2a to the SCA composite definition from step 1:

      ```
      <?xml version="1.0" encoding="UTF-8"?>
       <composite
        xmlns="http://www.osoa.org/xmlns/sca/1.0"
        xmlns:scafp="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
        targetNamespace="http://www.example.com"
        name="HelloWorldComposite">
          <component name="HelloWorldComponent">
              <scafp:implementation.osgiapp
                 applicationSymbolicName="helloworldApp"
                 applicationVersion="1.0.0"/>
              <service name="helloWorld">
                  <binding.sca>
              </service>
          </component>
      </composite>
      ```

      The example uses `binding.sca` for the service binding. The service can be made available over one or more of the other bindings that SCA supports.

The SCA service element is not required. If it is not specified, the service is made available over `binding.sca` by default.

3. Identify services to be provided from outside the OSGi application.
   a. Edit the Application-ImportService header in the OSGi application manifest so that it identifies one or more service interfaces to be imported.

      The following example header specifies that the `example.Greeting` service interface be imported:

      ```
      Application-ImportService: example.Greeting
      ```

      A Blueprint reference explicitly requests an imported service by filtering for the `service.imported` property. Remote services use pass-by-value semantics instead of pass-by-reference semantics for local services within the application. The following example shows a Blueprint component with such a reference:

      ```
      <blueprint xmlns="http://www.osgi.org/xmlns/blueprint/v1.0.0">
        <bean id="helloWorldComponent" class="example.HelloWorldImpl"
          <property name="greetingList" ref="greetingRef"/>
        </bean>
        <service id="helloWorld" ref="helloWorldComponent"
           interface="example.HelloWorld">
         <service-properties>
           <entry key="service.exported.interfaces" value="*"/>
         </service-properties>
        </service>
        <reference-list id="greetingRef" interface="example.Greeting"
           filter="(&amp;(service.imported=*))"/>
      </blueprint>
      ```

   b. Configure an SCA reference that corresponds to each imported service in the component.

      Use the fully qualified interface name for the SCA reference name.

      For example, add the `example.Greeting` reference that is shown in the Blueprint component from step 3 to the SCA composite definition from step 2:

      ```
      <?xml version="1.0" encoding="UTF-8"?>
       <composite
        xmlns="http://www.osoa.org/xmlns/sca/1.0"
        xmlns:scafp="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
        targetNamespace="http://www.example.com"
        name="HelloWorldComposite">
          <component name="HelloWorldComponent">
              <scafp:implementation.osgiapp
                 applicationSymbolicName="helloworldApp"
                 applicationVersion="1.0.0"/>
              <service name="helloWorld">
                  <binding.sca>
              </service>
              <reference name="example.Greeting">
                  <binding.sca uri="MyGreetingComponent">
              </reference>
          </component>
      </composite>
      ```

      The example uses `binding.sca` for the reference binding. The reference can use one or more of the other bindings that SCA supports.

      An SCA reference for an `implementation.osgiapp` component implicitly has 0-to-many for the multiplicity attribute (`multiplicity='0..n'`). This means you can wire the reference to 0, 1, or multiple services depending upon the requirements of the application. As to the multiplicity attribute:

      - A blueprint `reference-list` element selects multiple services. The blueprint implementation cannot make any assumptions about the order of the services in the reference list compared to the order of bindings in the composite definition.
      - A blueprint `reference` element selects a single service. If the SCA reference provides more than one binding, the selection of which binding is used is unspecified. If the SCA reference does not provide any bindings, the dependency is unsatisfied. If the reference is mandatory, the bean might not start.

      You can override the multiplicity attribute on the SCA reference, setting 1-to-many (`'1..n'`) or 1-to-1 (`'1..1'`), to ensure that a particular number of bindings is specified.

### Results

The OSGi application is defined as an SCA component.

### What to do next

Deploy the OSGi application and the SCA composite that uses the application as composition units of the same business-level application. You can use the administrative console or wsadmin commands to create a business-level application, import the EBA file and SCA composite as assets, and then add the EBA and SCA assets as composition units to the business-level application.

## SCA programming model support in OSGi applications

This topic describes the features of the Service Component Architecture (SCA) programming model that can be used with OSGi applications.

- Annotations
- Authorization policy
- Mapping of Blueprint transaction metadata to SCA service and reference transaction intents
- Using intents in an OSGi application
- Interface definition
- Custom wire format and operation selector
- Service Data Objects (SDO) version 2.1.1 with OSGi applications

### Annotations

The following annotations from the org.osoa.sca.annotations package are supported within the interface classes in an OSGi application:

- @OneWay
- @Remotable

  When an OSGi application is used as an SCA component, its service and reference interfaces are automatically treated as remotable. The @Remotable annotation is not required. However, if you want to use the same Java source interface in other contexts, it might need to contain the @Remotable annotation:

  – If you copy the interface to the SCA asset and specify it in an `interface.java` element for an `implementation.osgiapp` service or reference, the interface must contain the @Remotable annotation. Otherwise, an interface incompatibility error occurs.

  – If you wire `implementation.java` and `implementation.osgiapp` components to each other, the interface must contain the @Remotable annotation. Otherwise, the `implementation.java` component considers the interface to be local and an interface incompatibility error occurs.

No annotations from the org.osoa.sca.annotations package are supported within the implementation classes in an OSGi application.

### Authorization policy

You can attach an SCA policy set containing authorization policy statements to an `implementation.osgiapp` component. The policy set applies to all services of the component. It applies only when the services are started through SCA service bindings, and not when the OSGi application internally uses its services.

SCA does not support the use of the org.osoa.sca.annotations.PolicySet annotation or the annotations in the javax.annotation.security package in Blueprint implementation classes.

The configuration of role-based security for SCA components is independent of the configuration of role-based security for a Web application bundle (WAB). In other words, the roles and role mappings used for SCA components and for WABs are separate.

## Mapping of Blueprint transaction metadata to SCA service and reference transaction intents

Use the transaction metadata in the Blueprint component definition to define the transactional environment of an `implementation.osgiapp` component

You can use the propagatesTransaction, suspendsTransaction, transactedOneWay, and exactlyOnce intents with the services and references of an `implementation.osgiapp` component. Use the correct intents for the transaction metadata in the Blueprint component definition. SCA does not detect mismatches. The following table shows valid combinations of Blueprint transaction metadata and transaction intents.

*Table 139. Valid combinations of transaction intents in OSGi applications. Use valid transaction intents for services and references of an `implementation.osgiapp` component.*

| Transaction definition in Blueprint component | Valid service intents | Valid reference intents |
|---|---|---|
| Required | • propagatesTransaction<br>• transactedOneWay<br>• exactlyOnce | • propagatesTransaction<br>• suspendsTransaction<br>• transactedOneWay |
| Mandatory | • propagatesTransaction<br>• transactedOneWay<br>• exactlyOnce | • propagatesTransaction<br>• suspendsTransaction<br>• transactedOneWay |
| RequiresNew | suspendsTransaction | • propagatesTransaction<br>• suspendsTransaction<br>• transactedOneWay |
| Supports | propagatesTransaction | • propagatesTransaction<br>• suspendsTransaction |
| NotSupported | suspendsTransaction | |
| Never | | |

The managedTransaction.global, managedTransaction.local, and noManagedTransaction intents do not apply for `implementation.osgiapp` components.

Not all service bindings support all intents. For information about each intent, consult the SCA Transaction Policy specification.

The SCA run time does not effect the propagatesTransaction or suspendsTransaction behavior on an SCA service. Use the correct transaction definition in the Blueprint component to achieve the wanted behavior. The main purpose of using an intent is to document a requirement to use a binding that supports it.

## Using intents in an OSGi application

A Blueprint service can require a policy intent by using the `service.exported.intents` service property as shown in the following example:

```
<service ref="componentImplementation"
   interface="example.MyTransactionalServiceInterface">
   <service-properties>
      <entry key="service.exported.intents" value="propagatesTransaction"/>
   </service-properties>
</service>
```

Using the `service.exported.intents` property has the same effect as putting the intent in the SCA service definition.

The Application-ImportService header in the OSGi application manifest can filter for a particular policy intent on an imported service:

```
Application-ImportService: example.Greeting;filter="(&(service.intents=propagatesTransaction))"
```

If the SCA reference does not provide the intent, no services are imported.

## Interface definition

It is not required to specify an interface element on a component service or component reference. You can specify an interface to enforce a given contract with the implementation. In this case, the interface must be compatible with the implementation as stated in the SCA specification. The SCA run time cannot validate that the interfaces are compatible until the business-level application is started.

If you specify an `interface.java` or `interface.wsdl` element, it must refer to a Java class or WSDL file that is packaged in the SCA asset, or that is imported from a shared asset.

## Custom wire format and operation selector

The JMS binding enables you to provide classes that customize its function. The classes can provide:

- A wire format handler that transforms data between the application interface and a JMS Message
- A custom operation selector to determine the operation name from a JMS Message

You can package these classes in a bundle within the enterprise bundle archive (EBA). This is necessary to have access to Java packages inside the EBA bundles. For example, if a wire format handler needs to transform the content of a JMS Message into user-defined types defined within the EBA, the handler must be packaged in the EBA. To indicate that the handler is packaged in the EBA, you must use the `deferLoad` attribute; for example:

```
<composite
  xmlns="http://www.osoa.org/xmlns/sca/1.0"
  xmlns:scafp="http://www.ibm.com/xmlns/prod/websphere/sca/1.0/2007/06"
  targetNamespace="http://www.example.com"
  name="MyOSGiComposite">
    <component name="MyOSGiComponent">
      <scafp:implementation.osgiapp ...>
        <service name="MyOSGiService">
          <binding.jms>
            <activationSpec ...>
              <scafp:wireFormat.jmsCustom
                      class="example.WireHandler" deferLoad="true"/>
              <scafp:operationSelector.jmsCustom
                      class="example.OpSelector" deferLoad=="true"/>
          </binding.jms>
        </service>
    </component>
</composite>
```

## Service Data Objects (SDO) version 2.1.1 with OSGi applications

You can use Service Data Objects version 2.1.1 over SCA default, Web service, JMS and HTTP bindings for an `implementation.osgiapp` component service. Package schema definition (XSD) files in an SCA asset, or import XSD files from a shared asset.

The following limitations apply when you use SDO with an `implementation.osgiapp` component:

- You must invoke the OSGi application over a supported SCA service binding, such as an SCA default, Web service, JMS or HTTP binding. In particular, you cannot use the SDO functionality in your OSGi

application when you access the OSGi application over HTTP using the Web container access path that you typically use to access OSGi application code packaged in an OSGi Web application bundle (WAB).

- The product does not support the injection of the SCA-managed default HelperContext object using annotation. However, you can implement an application programming interface (API), which uses the commonj.sdo.helper.SDO class, to access the default HelperContext object. For more information about the HelperContext object, see the documentation about accessing default HelperContext objects in SCA applications
- You cannot use SDO in an OSGi application that is accessed over the SCA service bindings `binding.atom` or `binding.ejb`.

**Note:** If your application previously used SDO version 1.0.0, change the Import-Package to:

```
Import-Package: commonj.sdo;version="[2.0.0,3.0.0)"
```

# Deploying OSGi applications that use SCA

You can deploy OSGi and Service Component Architecture (SCA) applications to servers or clusters as assets, which you add to a business-level application by creating composition units.

## Before you begin

This topic assumes that you have already created an OSGi application packaged as an enterprise bundle archive (EBA) file and an SCA composite definition packaged as a Java archive (JAR) file.

An SCA composite packaged with a Web archive (WAR) file cannot use the `implementation.osgiapp` component.

## About this task

To deploy an OSGi application that uses SCA, create a business-level application that includes the EBA and SCA assets. You can use the administrative console or wsadmin commands to create the business-level application, import the EBA file and SCA composite as assets, and then add the EBA and SCA assets as composition units to the business-level application.

An EBA composition unit consists of the imported asset (the EBA file), plus any configuration information for the OSGi application context roots, virtual hosts, and resource bindings. If a deployed OSGi application is to be extended using composite bundles extensions, apply all extensions to the EBA composition unit (`cu`) and update the OSGi application to the latest deployment version. You must install all service import and exports that are provided by composite bundle extensions before you can add the SCA asset as a composition unit to a business-level application. For information on using and deploying OSGi composite bundle extensions, see the topic on extending a deployed OSGi application.

For `implementation.osgiapp`, the component implementation value for the composition unit is the application symbolic name and version.

The following deployment restrictions apply to EBA files:

- Import an EBA file into only one asset.
- Add an EBA asset to only one business-level application.

For information about these and other restrictions, see the topic on multiple SCA implementation packaging considerations.

## Procedure

1. Create a business-level application.

*Table 140. Ways to create SCA business-level applications. You can create a business-level application that has OSGi and SCA assets using the administrative console or wsadmin scripts.*

| Option | Method |
|---|---|
| Administrative console business-level application creation wizard | Click **Applications** > **New Application** > **New Business Level Application** and follow instructions in the wizard.<br><br>For example use of the console to create a business-level application that has an SCA asset, see Example: Creating an SCA business-level application with the console. |

2. Import OSGi, SCA, or other assets needed by your business-level application.
3. Add the EBA asset as a composition unit to the business-level application.

   You must add the EBA asset before the SCA asset that references it.
4. Add the SCA asset as a composition unit to the business-level application.

   By default, the product assigns the SCA composition unit a higher starting weight value than the value for the OSGi composition unit. When using `implementation.osgiapp`, the SCA composition unit must start after the referenced OSGi composition unit starts. Thus, the SCA composition unit must have a higher starting weight value than the OSGi composition unit. If you override the default values and set a higher starting weight value for the OSGi composition unit than for the SCA composition unit, the business-level application does not start.

   **Note:** If a validation error occurs when adding the SCA asset, saying that a service is not found, ensure that the following conditions exist:
   - The service name matches the name of a blueprint service
   - The Blueprint service uses the `services.exported.interfaces` property to export its interface
   - The interface is included in the Application-ExportService header of the application manifest

   The absence of these conditions can cause the validation error. The error resembles the following:

```
com.ibm.wsspi.management.bla.op.OpExecutionException: CWSAM0105E:
The following Service Component Architecture (SCA) Validation errors caused the
CreateScaCodeGen step to fail:
  Service not found for component service:
   Component = HelloWorldComponent Service = helloWorld
```

## Results

The business-level application has OSGi and SCA composition units. You can now start the business-level application.

If the ServiceRuntimeException `Unable to access OSGi application framework` occurs when starting the business-level application, ensure that the SCA composition unit has a higher starting weight than the EBA composition unit.

If the ServiceRuntimeException `Unable to obtain service service from application` occurs, check `SystemOut.log` and `SystemErr.log` files for messages from the Blueprint container indicating that the run time cannot start the Blueprint service.

If the java.lang.TypeNotPresentException occurs when starting the business-level application, a bundle that uses one of the supported SCA annotations is not importing the org.osoa.sca.annotations package. Update the bundle manifest to import this package.

**Note:** This topic references one or more of the application server log files. Beginning in WebSphere Application Server Version 8.0 you can configure the server to use the High Performance

Extensible Logging (HPEL) log and trace infrastructure instead of using `SystemOut.log` , `SystemErr.log`, `trace.log`, and `activity.log` files or native z/OS logging facilities. If you are using HPEL, you can access all of your log and trace information using the LogViewer command-line tool from your server profile bin directory. See the information about using HPEL to troubleshoot applications for more information on using HPEL.

## What to do next

If you must delete a composition unit from the business-level application, delete the SCA composition unit before attempting to delete the EBA composition unit, otherwise the product returns an error. An EBA composition unit that provides the implementation cannot be deleted until the SCA composition unit that uses the `implementation.osgiapp` is deleted.

## Multiple SCA implementation packaging considerations

The product supports several implementation technologies that can provide the business logic for SCA service components. Because a primary architectural objective of SCA is to enable you to combine existing services together, it is easy to assume that a single composite with multiple components might have different implementation technologies. However, there are restrictions that limit packaging of multiple SCA implementations.

### Business-level application deployment constraints

Before deploying an SCA application, particularly one that uses an OSGi application, consider the following constraints:

- Collocation

  SCA composites can be comprised of a variety of implementation frameworks. Packaging formats for these frameworks include, for example, enterprise archive (EAR) files for Java Platform, Enterprise Edition (Java EE) applications or enterprise bundle archive (EBA) files for OSGi applications. An SCA business-level application must contain both the framework packaging format and the SCA composite that uses it.

  In a Network Deployment environment, when deploying an `implementation.osgiapp` in an SCA composition unit, the EBA composition unit used for the implementation must be in the same business-level application and targeted to the same server or cluster as the SCA composition unit.

- Artifacts or shared libraries

  Business-level applications support shared libraries. It typically is good practice to package interface artifacts (Java interface classes or WSDL/XSD artifacts) in a shared library. Services in applications configured in a business-level application can reference the shared library.

  However, OSGi applications do not support shared configuration libraries. You must package Java interface and WSDL/XSD artifacts in both the SCA contribution Java archive (JAR) file and the EBA asset that is configured in the business-level application.

- Only one deployment

  Only one instance of a given OSGi application, packaged as an EBA file, can be deployed in a Network Deployment cell. An EBA file can contain only one OSGi application. An EBA asset can contain only one EBA file. An EBA asset can be added to only one business-level application, which is scoped at cell-level. Therefore, you can specify only once that a given OSGi application be an SCA implementation.

  To get around this constraint, you can connect to a deployed OSGi application from other applications in the cell, but you cannot include the business logic in another composite.

### Class loading

A purpose of the OSGi application framework is to build a class loader structure that is wholly defined by the OSGi service registry and OSGi application design, and avoid class loader problems that affect Java EE servers.

If your applications use different implementation technologies, differences in class loader structures might cause the SCA run time to copy objects from one environment to another. OSGi applications are remote-only interfaces that do not permit pass-by-reference behavior.

Your SCA application must use correct semantics for local and remote interfaces.

## Using Spring 2.5.5 containers in SCA applications

You can use the Service Component Architecture (SCA) programming model to invoke beans that follow the Java 2 Platform, Standard Edition (J2SE) programming model in a Spring 2.5.5 container. The product supports components implemented with Spring Framework that use `<implementation.spring>` in composite definitions.

### Before you begin

Before you start the procedure in this topic, do the following:

1. Become familiar with the SCA Spring Component Implementation 1.0.0 specification and Spring 2.5.5 programming. You must use Spring 2.5.5 for the SCA composite component implementation. The product does not support other levels of Spring.

   The product only supports the Spring Framework using the J2SE programming model. Local Java Naming and Directory Interface (JNDI) lookups are not supported, thus the product does not support the Spring Framework using the Java Platform, Enterprise Edition (Java EE) 5 programming model. Any attempts by a Spring container to perform a local JNDI lookup fail.
2. Decide whether to use `implementation.spring` or `implementation.jee` for your Spring application.

   The procedure in this topic discusses using `implementation.spring` in an SCA component implementation. If a Spring application is, in fact, a specialized Java EE application, instead of using `implementation.spring`, you can use `implementation.jee` to define the SCA component implementation and enable the Spring application to be part of an SCA component.

   For example, if a Spring application is packaged in a web module (WAR), then you can use an enterprise archive (EAR) that contains the WAR file as a component implementation using `implementation.jee`. The Spring application works like before and the Java EE context is not affected. Spring beans are not available in an SCA domain; however, other modules that are compatible with `implementation.jee` within the EAR file can participate in SCA.

   For information on deploying a Spring application with `implementation.jee`, see the topic on using existing Java EE modules and components as SCA implementations.
3. If you decide to use `implementation.spring` and you want beans in your Spring application to perform JNDI lookups, set `com.ibm.websphere.naming.WsnInitialContextFactory` as a property for the beans.

   You can use globally defined JNDI resources, such as databases and connection factories, in a Spring bean definition with `implementation.spring`. However, you must set a Spring JNDI template bean that has been configured to reference the WebSphere initial context factory, `com.ibm.websphere.naming.WsnInitialContextFactory`, as a property for beans performing JNDI lookups. For example, the following bean definitions specify that the `myJndiResource` bean use the WebSphere initial context factory:

   ```
   <bean id="myJndiResource" class="org.springframework.jndi.JndiObjectFactoryBean">
     <property name="jndiName" value="jdbc/myJndiResource"/>
     <property name="lookupOnStartup" value="true"/>
     <property name="cache" value="true"/>
     <property name="jndiTemplate" ref="wasJndiTemplate"/>
   </bean>

   <bean id="wasJndiTemplate" class="org.springframework.jndi.JndiTemplate">
     <property name="environment">
       <props>
         <prop key="java.naming.factory.initial">com.ibm.websphere.naming.WsnInitialContextFactory</prop>
       </props>
     </property>
   </bean>
   ```

The SCA container for implementation.spring does not run in a Java EE container, so it does not have access to the Java EE local JNDI namespace. By specifying that your Spring beans use the WebSphere initial context factory, you can prevent java:comp/ext from being prepended to the JNDI name during lookup.

## About this task

You can use a Spring application context as an implementation within an SCA composite component. Define the implementation using Spring 2.5.5. A Spring application context provides a complete composite, exposing services and using references using SCA.

A component that uses Spring for an implementation can wire SCA services and references without introducing SCA metadata into the Spring configuration. Generally, the Spring context knows little about the SCA environment.

## Procedure

1. Define a component implementation that uses the Spring Framework in a composite definition.

   The Spring component implementation in a composite definition has the following format:

```
<implementation.spring location="targetURI"/>
```

   The location attribute of the element specifies the target uniform resource indicator (URI) of a directory, or the fully qualified path that contains the Spring application context files.

   There are two ways that you can specify the target URI in the location attribute:

   - Specify a fully qualified path:

```
<implementation.spring location="./spring/application-context.xml"/>
```

   - Specify a directory:

```
<implementation.spring location="./spring"/>
```

     The target URI specifies the resource as a directory, here named spring, that has all the Spring-related files. To point to one application context, a META-INF/MANIFEST.MF file in that directory must contain a Spring-Context header of the format Spring-Context: *path*, where *path* is a relative path with respect to the location URI. For example:

```
Spring-Context: META-INF/spring/application-context.xml
```

     If the META-INF/MANIFEST.MF file does not exist or does not contain the Spring-Context header, then the product builds an application context using the application-context.xml file in the META-INF/spring directory. If the META-INF/spring/application-context.xml file does not exist, then the application does not deploy.

2. Optional: Override implicit mapping of Spring resource to SCA resources.

   By default, SCA implicitly maps Spring resources to SCA resources as follows:

   - Each <bean/> becomes <sca:service/>.
   - Each unresolved <property/> becomes <sca:reference/> if typed by an interface.
   - Each unresolved <property/> becomes <sca:property/> if not typed by an interface.

   You can override this default mapping by using the SCA XML extensions in the Spring context to create explicit declarations. You typically do this to enable the Spring container to decorate the bean using, for example, Spring Aspect-Oriented Programming (AOP). The SCA XML extensions are defined as follows:

   - <sca:service/> defines each service exposed by the context.
   - <sca:reference/> defines each reference exposed by the context.
   - <sca:property/> defines each property exposed by the context.<sca:property/> must be a bean class and not a primitive type.

   For example, the properties checkingAccountService, calculatorService, and stockQuoteService defined in the following Spring configuration are declared explicitly as SCA beans in a Spring application context using the <sca:reference> element:

```
<beans>
  <bean id="AccountServiceBean" class="bigbank.account.AccountServiceImpl">
    <property name="calculatorService" ref="calculatorService"/>
    <property name="stockQuoteService" ref="stockQuoteService"/>
    <property name="checkingAccountService" ref="checkingAccountService"/>
    <!-- Some implicit references and properties follow. A property with a reference
         not satisifed * within the Spring application context. -->
    <property name="savingsAccountService" ref="savingsAccountService"/>
    <property name="stockAccountService" ref="stockAccountService"/>
    <property name="currency" value="EURO"/>
  </bean>
  <sca:reference name="checkingAccountService" type="bigbank.account.checking.CheckingAccountService"/>
  <ca:reference name="calculatorService" type="bigbank.calculator.CalculatorService"/>
  <sca:reference name="stockQuoteService" type="bigbank.stockquote.StockQuoteService"/>
</beans>
```

3. If you completed step 2, to use the SCA XML extensions you must add the SCA schema to the application context.

   Add the SCA schema, `http://www.osoa.org/xmlns/sca/1.0/spring-sca.xsd` , to the application context. Specify a Spring application context that defines the SCA schema namespace and makes the Spring application aware of the SCA-related beans; for example:

```
<beans xmlns="http://www.springframework.org/schema/beans"
       xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
       xmlns:sca="http://www.springframework.org/schema/sca"
       xsi:schemaLocation="
         http://www.springframework.org/schema/beans
         http://www.springframework.org/schema/beans/spring-beans.xsd
         http://www.springframework.org/schema/sca
         http://www.osoa.org/xmlns/sca/1.0/spring-sca.xsd">
  <sca:service name="StockQuoteService"
       type="bigbank.stockquote.StockQuoteService" target="StockQuoteServiceBean"/>
  <bean id="StockQuoteServiceBean" class="bigbank.stockquote.StockQuoteImpl">
  </bean>
</beans>
```

   For more information about defining an application context, see the reference documentation provided by the Spring source community. For more information about the SCA schema, see the SCA Spring Implementation specification.

4. Package the SCA application context file in your service Java archive (JAR) file at the location specified in your composite definition.

   For example, package the SCA application context file in a Spring service JAR file is named `helloworld-spring.jar`.

5. Create a Spring runtime JAR file that contains Spring and product SCA runtime files.

   Because the Spring runtime binary files are not shipped with the product, you must create an asset that contains three Spring framework JAR files and one product JAR file. Create the asset as follows:

   a. If you do not have the Spring 2.5.5 framework binary files, go to Spring Community Downloads at `http://www.springsource.com/download/community?project=` and download `spring-framework-2.5.5.zip`.

      After you download the compressed `.zip` file, extract it to a temporary directory.

   b. Create an empty directory; for example, `C:\SpringAsset`.

   c. Copy the Spring 2.5.5 framework binary files `spring-beans.jar`, `spring-context.jar`, and `spring-core.jar` to the empty directory.

      If the Spring application requires transaction support, copy all the Spring JAR files into the empty directory. The AspectJ Weaver library files are also required for transaction support.

   d. Copy the *app_server_root*`/optionalLibraries/sca/SCA-implementation-spring-runtime-1.0.1.jar` file to the same directory in which you placed the three Spring JAR files.

      **Note:** If you install a product maintenance package, update the `SpringSharedLibAsset.jar` with the newer version of the *app_server_root*`/optionalLibraries/sca/SCA-implementation-spring-runtime-1.0.1.jar` file.

   e. Create a JAR file named `SpringSharedLibAsset.jar` that contains the four JAR files you placed in the `C:\SpringAsset` directory.

      For example, at a command prompt, enter the following commands:

      1) `cd C:\SpringAsset`

2) `jar –cvf SpringSharedLibAsset.jar *.jar`

For performances reasons, the JAR file must be named `SpringSharedLibAsset.jar`.

f. Verify that the `SpringSharedLibAsset.jar` file contains all four JAR files in the root directory.

6. Import the Spring runtime JAR file as an asset.

   To import `SpringSharedLibAsset.jar` as an asset using a wsadmin Jython command, enter the following command:

```
AdminTask.importAsset('-source SpringSharedLibAsset.jar -storageType FULL')
```

   You can also use the administrative console.

7. Import the Spring service JAR file as an asset with a dependency on the Spring runtime asset.

   Suppose that your Spring service JAR file is named `helloworld-spring.jar`. Import your Spring service JAR file, `helloworld-spring.jar`, and create a dependency on the Spring runtime asset, `SpringSharedLibAsset.jar`. The dependency enables the product to access the necessary Spring classes. You can import the Spring service JAR file using the following wsadmin Jython command:

```
AdminTask.importAsset('-source helloworld-spring.jar -storageType FULL -AssetOptions
 [[ helloworld-spring.jar helloworld-spring.jar "" "" "" spec=zip assetname=SpringSharedLibAsset.jar
 "" false]]]')
```

   Alternatively, you can use the administrative console to import the asset with a dependency:

   a. On the administrative console, click **Applications** > **Application Types** > **Assets**.

   b. On the Assets page, click **Import**.

   c. On the Upload asset page, specify the full path name of the service JAR file and click **Next**.

   d. On the Select options for importing an asset page, specify a dependency.

      1) Click **Manage Relationships**. The button is near the bottom of the page. The product detects asset relationships automatically by matching the dependencies defined in the JAR manifest with the assets that are already imported into the administrative domain.

      2) Select your Spring runtime JAR file, such as `SpringSharedLibAsset.jar`, click **>>** to move the JAR file to the **Selected** list.

      3) Click **OK**.

         Under **Current asset relationships**, the asset name is shown; for example:

```
WebSphere:assetname=SpringSharedLibAsset.jar
```

      4) Click **Next**.

   e. Click **Finish**.

   f. After the product imports the asset, click **Save**.

### Results

The Spring runtime JAR file and Spring service JAR file are imported assets available for use in a business-level application. The Spring service JAR asset has a dependency on the Spring runtime asset.

### What to do next

Add the JAR assets that you created to an SCA business-level application.

To learn about Spring implementation features that the product supports but which are not defined in the SCA Spring Implementation specification, see "Additional Spring component implementation features."

## Additional Spring component implementation features

The product supports Spring implementation features that are not defined in the Service Component Architecture (SCA) Spring Implementation specification.

The product supports the following features:

- Constructor injection

The product supports the injection of SCA references and properties within Spring bean constructors. Define <constructor-arg> elements that specify the appropriate type of the SCA references or properties to use. If the elements do not specify the type attribute, then at least specify the index attribute. The product only supports constructor injection when the Spring bean has a single constructor.

- Using the ClassPathXmlApplicationContext bean definition

  When the ClassPathXMLApplicationContext bean definition is in an application context, only the beans and properties defined in the top-level application context can be mapped, either explicitly or implicitly, to SCA resources.

  The product does not support using a FileSystemXMLApplicationContext definition to load an application context file.

- <import> elements in application context files

  The product supports use of <import> elements in application context files. Each <import> element points to an application context XML file; for example:

```
<bean>
  <import resource="services.xml"/>
  <import resource="resources/messageSource.xml"/>
  <import resource="/resources/themeSource.xml"/>
  <bean id="bean1" class="..."/>
  <bean id="bean2" class="..."/>
</beans>
```

# Directory conventions

References in product information to *app_server_root*, *profile_root*, and other directories imply specific default directory locations. This topic describes the conventions in use for WebSphere Application Server.

## Default product locations (distributed)

The following file paths are default locations. You can install the product and other components or create profiles in any directory where you have write access. Multiple installations of WebSphere Application Server - Express products or components require multiple locations. Default values for installation actions by root and nonroot users are given. If no nonroot values are specified, then the default directory values are applicable to both root and nonroot users.

*app_client_root*

*Table 141. Default installation root directories for the Application Client for IBM WebSphere Application Server.*

*This table shows the default installation root directories for the Application Client for IBM WebSphere Application Server.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/AppClient (Java EE Application client only)<br>HP-UX Linux Solaris /opt/IBM/WebSphere/AppClient (Java EE Application client only)<br>Windows C:\Program Files\IBM\WebSphere\AppClient |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/AppClient (Java EE Application client only)<br>Windows C:\IBM\WebSphere\AppClient |

*app_server_root*

*Table 142. Default installation directories for WebSphere Application Server.*

*This table shows the default installation directories for WebSphere Application Server - Express.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/AppServer<br>HP-UX Linux Solaris /opt/IBM/WebSphere/AppServer<br>Windows C:\Program Files\IBM\WebSphere\AppServer |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/AppServer<br>Windows *user_home*\IBM\WebSphere\AppServer |

*component_root*

The component installation root directory is any installation root directory described in this topic. Some programs are for use across multiple components—in particular, the Web Server Plug-ins, the Application Client, and the IBM HTTP Server. All of these components are part of the product package.

*gskit_root*

IBM Global Security Kit (GSKit) can now be installed by any user. GSKit is installed locally inside the installing product's directory structure and is no longer installed in a global location on the target system. The following list shows the default installation root directory for Version 8 of the GSKit, where *product_root* is the root directory of the product that is installing GSKit, for example IBM HTTP Server or the web server plug-in.

AIX HP-UX Linux Solaris

*product_root*/gsk8

Windows

*product_root*\gsk8

*profile_root*

*Table 143. Default profile directories.*

*This table shows the default directories for a profile named profile_name on each distributed operating system.*

| User | Directory |
|---|---|
| Root | AIX /usr/IBM/WebSphere/AppServer/profiles/*profile_name*<br>HP-UX Linux Solaris /opt/IBM/WebSphere/AppServer/profiles/*profile_name*<br>Windows C:\Program Files\IBM\WebSphere\AppServer\profiles*profile_name* |
| Nonroot | AIX HP-UX Linux Solaris *user_home*/IBM/WebSphere/AppServer/profiles<br>Windows *user_home*\IBM\WebSphere\AppServer\profiles |

*plugins_root*

*Table 144. Default installation root directories for the Web Server Plug-ins.*

# Chapter 25. Developing Scheduler service

This page provides a starting point for finding information about the scheduler service, a WebSphere programming extension responsible for starting actions at specific times or intervals.

Schedulers are persistent and transactional timer services that run Enterprise JavaBeans methods or send Java Message Service messages using any Java Message Service messages using any Java Platform, Enterprise Edition (Java EE) server application.

The scheduler service helps minimize IT costs and increase application speed and responsiveness by maximizing utilization of existing computing resources.

The scheduler service provides the ability to reliably process workloads using parallel processing and schedule resource-intensive tasks to process during low traffic off-hours.

## Developing and scheduling tasks

To develop and schedule tasks, use a configured scheduler.

### Procedure

1. Look up a configured scheduler. Refer to the Accessing schedules topic. Each configured scheduler is available from two different programming models:
   - A Java Platform, Enterprise Edition (Java EE) server application, such as a servlet or Enterprise JavaBeans (EJB) component, can use the Scheduler API. Schedulers are accessed by looking them up using a Java Naming and Directory Interface (JNDI) name or resource reference.
   - Java Management Extensions (JMX) applications, such as wsadmin scripts, can use the Scheduler API using WASScheduler MBeans.
2. Develop the task.

   The Scheduler API supports different implementations of the TaskInfo interface, each of which can be used to schedule a particular type of work. Refer to the Developing a task that calls a session bean topic and Develop a task that sends a Java Message Service (JMS) message topic for details. The task object that is referenced in the Develop a task that sends a Java Message Service (JMS) message topic can send a JMS message to either a queue or a topic.

   **Attention:** Creating and manipulating scheduled tasks through the Scheduler interface is only supported from within the EJB container or Web container (Enterprise beans or servlets). Looking up and using a configured scheduler from a Java EE application client container is not supported.
3. Receive scheduler notifications. A notification sink is set on a task in order to receive the notification events that are generated by a scheduler when it performs an operation on the task.
4. Use custom calendars. You can assign a UserCalendar session bean to a task that allows schedulers to use custom and predefined date algorithms to determine when a task should run. Refer to the UserCalendar interface topic for details.
5. Submit tasks to a scheduler. After a TaskInfo object has been created, it can be submitted to the scheduler for task creation by calling the Scheduler.create() method.
6. Manage tasks with a scheduler.
7. Secure tasks with a scheduler.

### Example

You can use the SIMPLE and CRON calendars from any Java EE application. This example illustrates the process.

- Using default scheduler calendars

© Copyright IBM Corp. 2011

**Using default scheduler calendars.** The following code examples illustrates how to use connections correctly and incorrectly.

Using default scheduler calendars involves looking up the default UserCalendarHome Enterprise JavaBeans (EJB) home object, creating the UserCalendar bean and calling the applyDelta() method. For details on the applyDelta method as well as the syntax for the SIMPLE and CRON calendars, see UserCalendar interface topic.

```
import java.util.Date;
import javax.naming.InitialContext;
import javax.rmi.PortableRemoteObject;
import com.ibm.websphere.scheduler.UserCalendar;
import com.ibm.websphere.scheduler.UserCalendarHome;

// Create an initial context
InitialContext ctx = new InitialContext();

// Lookup and narrow the default UserCalendar home.
UserCalendarHome defaultCalHome=(UserCalendarHome)
 PortableRemoteObject.narrow(ctx.lookup(
      UserCalendarHome.DEFAULT_CALENDAR_JNDI_NAME),
    UserCalendarHome.class);

// Create the default UserCalendar instance.
UserCalendar defaultCal = defaultCalHome.create();

// Calculate a date using CRON based on the current
// date and time.  Return the next date that is
// Saturday at 2AM
Date newDate =
    defaultCal.applyDelta(new Date(),
        "CRON", "0 0 2 ? * SAT");
```

# Accessing schedulers

Each configured scheduler is available using the Scheduler API from a Java Platform, Enterprise Edition (Java EE) server application, such as a servlet or Enterprise JavaBeans (EJB) module. Use a Java Naming and Directory Interface (JNDI). name or resource reference to access schedulers. Each scheduler is also available using the Java™ Management Extensions (JMX) API, using its associated WASScheduler MBean.

## About this task

Scheduler and WASScheduler interfaces are the starting point for all scheduler activities. Each scheduler is independent and allows task life cycle operations, such as creating new tasks.

## Procedure

1. Locate schedulers using the javax.naming.Context.lookup() method from a Java EE server application, such as a servlet or EJB module like the following example:

   ```
   //lookup the scheduler to be used
   import com.ibm.websphere.scheduler.Scheduler;
   import javax.naming.InitialContext;
   Scheduler scheduler = (Scheduler)new InitialContext.lookup("java:comp/env/sched/MyScheduler");
   ```

2. Use wsadmin to locate a WASScheduler MBean using JACL scripting:

   ```
   set jndiName sched/MyScheduler

   # Map the JNDI name to the mbean name.  The mbean name is
   # formed by replacing the / in the JNDI namewith . and prepending
   # Scheduler_
   regsub -all {/} $jndiName "." jndiName
   set mbeanName Scheduler_$jndiName
   ```

```
puts "Looking-up Scheduler MBean $mbeanName"
set sched [$AdminControl queryNames WebSphere:*,type=WASScheduler,name=$mbeanName]
puts $sched
```

### Results

The scheduler is now available to use from a Java EE server application or from a JMX API client. To create a task see the topics, Developing a task that calls a session bean or Developing a task that sends a JMS message.

## Developing a task that calls a session bean

The Scheduler API and WASScheduler MBean API support different implementations of the TaskInfo interface, each of which can be used to schedule a particular type of work. This topic describes how to create a task to call a method on a TaskHandler session bean.

### About this task

To create a task to call a method on a TaskHandler session bean, use these steps.

### Procedure

1. Create a new enterprise application with an Enterprise JavaBeans (EJB) module. This application hosts the TaskHandler EJB module.
2. Create a stateless session bean in the EJB Module that implements the process() method in the com.ibm.websphere.scheduler.TaskHandler remote interface. Place the business logic you want created in the process() method. The process() method is called when the task runs. The Home and Remote interfaces must be set as follows in the deployment descriptor bean:
   - com.ibm.websphere.scheduler.TaskHandlerHome
   - com.ibm.websphere.scheduler.TaskHandler
3. Create an instance of the BeanTaskInfo interface by using the following example factory method. Using a JavaServer Pages (JSP) file, servlet or EJB component, create the instance as shown in the following code example. This code should coexist in the same application as the previously created TaskHandler EJB module:

   ```
   // Assume that a scheduler has already been looked-up in JNDI.
   BeanTaskInfo taskInfo = (BeanTaskInfo) scheduler.createTaskInfo(BeanTaskInfo.class)
   ```

   You can also use the wsadmin tool to create the instance as shown in the following JACL scripting example:

   ```
   set taskHandlerHomeJNDIName ejb/MyTaskHandler

   # Map the JNDI name to the mbean name.  The mbean name is formed by replacing the / in the jndi name
   # with . and prepending Scheduler_
   regsub -all {/} $jndiName "." jndiName
   set mbeanName Scheduler_$jndiName

   puts "Looking-up Scheduler MBean $mbeanName"
   set sched [$AdminControl queryNames WebSphere:*,type=WASScheduler,name=$mbeanName]
   puts $sched

   # Get the ObjectName format of the Scheduler MBean
   set schedO [$AdminControl makeObjectName $sched]

   # Create a BeanTaskInfo object using invoke_jmx
   puts "Creating BeanTaskInfo"
   set params [java::new {java.lang.Object[]} 1]
   $params set 0 [java::field com.ibm.websphere.scheduler.BeanTaskInfo class]

   set sigs [java::new {java.lang.String[]} 1]
   $sigs set 0 java.lang.Class
   ```

```
set ti [$AdminControl invoke_jmx $schedO createTaskInfo $params $sigs]
set bti [java::cast com.ibm.websphere.scheduler.BeanTaskInfo  $ti]
puts "Created the BeanTaskInfo object: $bti"
```

**Important:** Creating a BeanTaskInfo object does not add the task to the persistent store. Rather, it creates a placeholder for the necessary data. The task is not added to the persistent store until the create() method is called on a Scheduler, as described in the Submitting tasks to schedulers topic.

4. Set parameters on the BeanTaskInfo object. These parameters define which session bean is called and when. The TaskInfo interface contains various set() methods that you can use to control execution of the task, including when the task runs and what work the task does when it runs.

   The BeanTaskInfo interface requires that the TaskHandler Java™ Naming and Directory Interface (JNDI) name or TaskHandlerHome is set using the setTaskHandler method. If using the WASScheduler MBean API to set the task handler, then the JNDI name must be the fully-qualified global JNDI name.

   The TaskInfo interface specifies additional control points, as documented in the API documentation. Set parameters using the TaskInfo interface API method as shown in the following code example:

```
//create a date object which represents 30 seconds from now
java.util.Date startDate = new java.util.Date(System.currentTimeMillis()+30000);

//find the session bean to be called when the task starts
Object o = new InitialContext().lookup("java:comp/env/ejb/MyTaskHandlerHome");
TaskHandlerHome home = (TaskHandlerHome)javax.rmi.PortableRemoteObject.narrow(o,TaskHandlerHome.class);

//now set the start time and task handler to be called in the task info
taskInfo.setTaskHandler(home);
taskInfo.setStartTime(startDate);
```

   You can also set parameters using the following JACL scripting example:

```
# Setup the task
puts "Setting up the task..."
# Set the startTime if you want the task to run at a specific time, for example:
$bti setStartTime [java::new {java.util.Date long} [java::call System currentTimeMillis]]

# Set the StartTimeInterval so the task runs in 30 seconds from now
$bti setStartTimeInterval 30seconds

# Set JNDI name of the EJB which will get called when the task runs.  Since there is no
# application J2EE Context when the task is created by the MBean, this must be a
# global JNDI name.
$bti setTaskHandler $taskHandlerHomeJNDIName

# Do not purge the task when it's complete
$bti setAutoPurge false

# Set the name of the task.  This can be any string value.
$bti setName Created_by_MBean

# If the task needs to run with specific authorization you can set the tasks Authentication Alias
# Authentication aliases are created using the Admin Console.
# $bti setAuthenticationAlias {myRealm/myAlias}

puts "Task setup completed."
```

## Results

A BeanTaskInfo object has been created that contains all of the relevant data to call an EJB method.

## What to do next

Submit the task to a scheduler for creation.

# Developing a task that sends a Java Message Service message

The Scheduler API and WASScheduler MBean API support different implementations of the TaskInfo interface, each of which can be used to schedule a particular type of work. This topic describes how to create a task that sends a Java Message Service (JMS) message to a queue or topic.

## About this task

To create a task that sends a Java Message Service (JMS) message to a queue or topic, use these steps.

## Procedure

1. Create an instance of the MessageTaskInfo interface using the Scheduler.createTaskInfo() factory method. Using a JavaServer Pages (JSP) file, servlet or EJB container, create the instance as shown in the following code example:

```
//lookup the scheduler to be used
Scheduler scheduler = (Scheduler)new InitialContext.lookup("java:comp/env/Scheduler");

MessageTaskInfo taskInfo = (MessageTaskInfo) scheduler.createTaskInfo(MessageTaskInfo.class);
```

   You can also use the wsadmin tool, create the instance as shown in the following JACL scripting example:

```
# Sample create a task using MessageTaskInfo task type
# Call this mbean with the following parameters:
#    <scheduler jndiName>     = JNDI name of the scheduler resource,
#                               for example scheduler/myScheduler
#    <JNDI name of the QCF>   = The global JNDI name of the Queue Connection Factory.
#    <JNDI name of the Queue> = The global JNDI name of the Queue destination

set jndiName [lindex $argv 0]
set jndiName_QCF [lindex $argv 1]
set jndiName_Q [lindex $argv 2]

# Map the JNDI name to the mbean name.  The mbean name is formed by replacing the / in the jndi name
# with . and prepending Scheduler_
regsub -all {/} $jndiName "." jndiName
set mbeanName Scheduler_$jndiName

puts "Looking-up Scheduler MBean $mbeanName"
set sched [$AdminControl queryNames WebSphere:*,type=WASScheduler,name=$mbeanName]
puts $sched

# Get the ObjectName format of the Scheduler MBean
set schedO [$AdminControl makeObjectName $sched]

# Create a MessageTaskInfo object using invoke_jmx
puts "Creating MessageTaskInfo"
set params [java::new {java.lang.Object[]} 1]
$params set 0 [java::field com.ibm.websphere.scheduler.MessageTaskInfo class]

set sigs [java::new {java.lang.String[]} 1]
$sigs set 0 java.lang.Class

set ti [$AdminControl invoke_jmx $schedO createTaskInfo $params $sigs]
set mti [java::cast com.ibm.websphere.scheduler.MessageTaskInfo  $ti]
puts "Created the MessageTaskInfo object: $mti"
```

   **Attention:** Creating a MessageTaskInfo object does not add the task to the persistent store. Rather, it creates a placeholder for the necessary data. The task is not added to the persistent store until the create() method is called on a Scheduler, as described in the Submitting a task to a scheduler topic.

2. Set parameters on the MessageTaskInfo object. The TaskInfo interface contains various set() methods that can be used to control execution of the task, including when the task runs and what work the task does when it starts.

The TaskInfo interface specifies additional behavior settings, as documented in the API documentation. Using a JavaServer Pages (JSP) file, servlet or EJB container, create the instance as shown in the following code example:

```
//create a date object which represents 30 seconds from now
java.util.Date startDate = new java.util.Date(System.currentTimeMillis()+30000);

//now set the start time and the JNDI names for the queue connection factory and the queue
taskInfo.setConnectionFactoryJndiName("jms/MyQueueConnectionFactory");
taskInfo.setDestination("jms/MyQueue");
taskInfo.setStartTime(startDate);
```

You can also use the wsadmin tool, to create the instance as shown in the following JACL scripting example:

```
# Setup the task
puts "Setting up the task..."
# Set the startTime if you want the task to run at a specific time, for example:
$mti setStartTime [java::new {java.util.Date long} [java::call System currentTimeMillis]]

# Set the StartTimeInterval so the task runs in 30 seconds from now
$mti setStartTimeInterval 30seconds

# Set the global JNDI name of the QCF & Queue to send the message to.
$mti setConnectionFactoryJndiName $jndiName_QCF
$mti setDestinationJndiName $jndiName_Q

# Set the message
$mti setMessageData "Test Message"

# Do not purge the task when it's complete
$mti setAutoPurge false

# Set the name of the task.  This can be any string value.
$mti setName Created_by_MBean

# If the task needs to run with specific authorization you can set the tasks Authentication Alias
# Authentication aliases are created using the Admin Console.
# $mti setAuthenticationAlias {myRealm/myAlias}

puts "Task setup completed."
```

### Results

A MessageTaskInfo object has been created that contains all of the relevant data for a task that sends a JMS message.

### What to do next

Submit the task to a scheduler for creation, as described in the Submitting a task to a scheduler topic.

## Scheduling long-running tasks

The default behavior of the scheduler is designed to run business logic that runs for a short period of time. In version 6.0.2 and later, two API methods on the com.ibm.websphere.scheduler.TaskInfo interface help avoid some of the problems that can occur when running tasks for an extended time.

### About this task

The TaskInfo.setQOS method supports tasks with both a transactional and non-transactional quality of service. When running tasks that run for long periods, you can use the TaskInfo.QOS_ATLEASTONCE quality of service to run the task without a global transaction. This process prevents various timeout issues

that can occur when resources are held by a long-running transaction. See the Transactions and schedulers topic for details on the TaskInfo.setQOS method and how it can be used.

Using the TaskInfo.setExpectedDuration method, the scheduler can to adjust timeout values, as appropriate, for a given task for all qualities of service. The application server attempts to adjust various run-time parameters to accommodate the estimated run time of the task.

### Procedure

1. When you assemble the TaskInfo object with the Scheduler API or the WASScheduler MBean, use the following methods on the TaskInfo interface:
   a. Set the quality of service.
      1) If the task must be transactional, use the setQOS method with the QOS_ONLYONCE constant, which is the default, if not set.
      2) If the task does not need to be transactional, use the setQOS method with the QOS_ATLEASTONCE constant.
   b. Set the expected duration.
      1) Use the setExpectedDuration method to set the expected duration of the task in seconds.
2. Schedule the task using the Scheduler.create method.

### What to do next

View the Access schedulers topic.

## Receiving scheduler notifications

Various notification events are generated by a scheduler when it performs an operation on a task. These notifications events are described in this topic.

### About this task

The notification events generated by a scheduler when it performs a task include:

**Scheduled**
A task has been scheduled.

**Purged**
A task has been permanently deleted from the persistent store.

**Suspended**
A task was suspended.

**Resumed**
A task was resumed.

**Complete**
A task has run completely. If it was a repeating task, all repeats have been performed.

**Cancelled**
A task has been cancelled. It will not run again.

**Firing** A task is prepared to run.

**Fired** A task completed successfully.

**Fire failed**
A task could not run successfully.

To receive notification events, call the setNotificationSink() method on the TaskInfo interface before creating the task. The setNotificationSink() method enables you to specify the session bean that is to act as the callback, and a mask that restricts which events are generated.

### Procedure

1. Create a NotificationSink session bean. Create a stateless session bean that implements the handleEvent() method in the com.ibm.websphere.scheduler.NotificationSink remote interface. The handleEvent() method is called when the notification is fired. The Home and Remote interfaces can be set as follows in the bean's deployment descriptor:

   ```
   com.ibm.websphere.scheduler.NotificationSinkHome
   com.ibm.websphere.scheduler.NotificationSink
   ```

   The NotificationSink interface defines the following method:

   ```
   public void handleEvent(TaskNotificationInfo task) throws java.rmi.RemoteException;
   ```

2. Specify the notification sink session bean prior to submitting the task to the Scheduler using the TaskInfo interface API setNotificationSink() method.

   If using the WASScheduler MBean API to set the notification sink, then the Java™ Naming and Directory Interface (JNDI) name must be the fully-qualified global JNDI name. Using a JavaServer Pages (JSP) file, servlet or Enterprise JavaBeans (EJB) component, look up and set the notification sink on a task as shown in the following code example:

   ```
   TaskInfo taskInfo = ...
   Object o = new InitialContext().lookup("java:comp/env/ejb/NotificationSink");
   NotificationSinkHome home = (NotificationSinkHome )javax.rmi.PortableRemoteObject.narrow
   (o,NotificationSinkHome.class);
   taskInfo.setNotificationSink(home,TaskNotificationInfo.ALL_EVENTS);
   ```

   You can also use the wsadmin tool to set the notification sink callback session bean as shown in the following JACL scripting example:

   ```
   # Use the NotificationSinkHome's Global JNDI name
   # Assume that a TaskInfo was already created...
   $taskInfo setNotificationSink "ejb/MyNotificationSink"
   ```

3. Specify the event mask. The event mask is specified as an integer bitmap. You can either use an individual mask such as TaskNotificationInfo.CREATED to receive specific events, TaskNotificationInfo.ALL_EVENTS to receive all events or a combination of specific events. If you use Java, your script might look like the following example:

   ```
   int eventMask = TaskNotificationInfo.FIRED | TaskNotificationInfo.COMPLETE;
   taskInfo.setNotificationSink(home,eventMask);
   ```

   If you use JACL, your script might look like the following example:

   ```
   # Set the event mask based on two event constants.
   set eventmask [expr [java::field com.ibm.websphere.scheduler.TaskNotificationInfo FIRED] +
    [java::field com.ibm.websphere.scheduler.TaskNotificationInfo COMPLETE]]

   # Set our Notification Sink based on our global JNDI name AND event mask.
   # Note:  We need to use the full method signature here since the
   # method resolver can't always detect the right method.
   $taskInfo {setNotificationSink String int} "ejb/MyNotificationSink" $eventmask
   ```

### Results

A notification sink bean is now set on a TaskInfo object and can now be submitted to a scheduler using the create method.

## Submitting a task to a scheduler

This topic describes the process of submitting a task to a configured scheduler.

### Before you begin

This task assumes that you have already configured a scheduler and created and configured a TaskInfo object that calls a session bean or sends a Java Messaging Service (JMS) message.

### About this task

Once you have developed a TaskInfo object that contains all relevant data for a task, submit the task to a scheduler for creation. When the task is created, the scheduler runs it.

### Procedure

Create the task. After you configure TaskInfo, submit it to the appropriate scheduler, using the Scheduler API create method.

```
// Create the TaskInfo using the Scheduler that you already looked up and print out the Task ID
TaskStatus ts = scheduler.create(taskInfo);
System.out.println("Task created with id: " + ts.getTaskId()"
```

You can also create the task using the wsadmin tool as shown in the following JACL scripting example:

```
# Create the TaskInfo using the WASScheduler MBean that you previously located and print out the Task ID
puts "Creating the task..."

set params [java::new {java.lang.Object[]} 1]
$params set 0 $taskInfo

set sigs [java::new {java.lang.String[]} 1]
$sigs set 0 com.ibm.websphere.scheduler.TaskInfo

set taskStatus [java::cast com.ibm.websphere.scheduler.TaskStatus [$AdminControl invoke_jmx $schedO
 create $params $sigs]]

puts "Task Created.  TaskID= [$taskStatus getTaskId]"

puts $taskStatus
```

When the call to the create() method is complete, the task exists in the persistent store and is run at the time specified in the TaskInfo object. If a global transactional context is present on the thread, and the create() transaction rolls back or is aborted, the task does not run.
The TaskStatus object, which has been returned by the call to the create() method, contains information about the state of the task, as well as the task ID. The task ID is the unique identifier for this task, and is required if the task is to be suspended, resumed, cancelled, and so on, at a later time.

**Tip:** The TaskStatus object is only a snapshot of the current state of the task. Use the Scheduler.getStatus() method to receive the current state when needed.

## Task management methods using a scheduler

The scheduler provides several task management methods.

When a task is created by calling the create() method on a scheduler, a TaskStatus object is returned to the caller. The TaskStatus object contains the task ID, which is a unique identifier. The Scheduler API and WASScheduler MBean define several additional methods that pertain to the management of tasks, each of which accepts the task ID as a parameter. The following task management methods are defined:

**suspend()**
: Suspends a task. The task does not run until it has been resumed.

**resume()**
: Resumes a previously suspended task.

**cancel()**
: Cancels a task. The task is not run and cannot be resumed.

**purge()**
: Permanently deletes a cancelled task from the persistent store.

**getStatus()**
: Returns the current status of the task.

Use the following API example to create and cancel a task:

```
//Create the task.
TaskInfo taskInfo = ...
TaskStatus status = scheduler.create(taskInfo);

//Get the task ID
String taskId = status.getTaskId();

//Cancel the task. Specify the purgeAlso flag so that the task does not remain in the persistent store
scheduler.cancel(taskId,true);
```

Use the following example JACL script operations in the wsadmin tool to create and cancel a task:

```
set jndiName sched/MyScheduler

# Map the JNDI name to the mbean name.  The mbean name is
# formed by replacing the / in the jndi name with . and prepending
# Scheduler_
regsub -all {/} $jndiName "." jndiName
set mbeanName Scheduler_$jndiName

puts "Looking-up Scheduler MBean $mbeanName"
set sched [$AdminControl queryNames WebSphere:*,type=WASScheduler,name=$mbeanName]
puts $sched

# Get the ObjectName format of the Scheduler MBean
set schedO [$AdminControl makeObjectName $sched]

# Create a TaskInfo object...
# (Some code excluded...)
set params [java::new {java.lang.Object[]} 1]
$params set 0 $taskInfo

set sigs [java::new {java.lang.String[]} 1]
$sigs set 0 com.ibm.websphere.scheduler.TaskInfo

set taskStatus [java::cast com.ibm.websphere.scheduler.TaskStatus [$AdminControl invoke_jmx $schedO
 create $params $sigs]]

set taskID [$taskStatus getTaskId]
puts "Task Created.  TaskID= $taskID"

# Cancel the task using the Task ID from the TaskStatus object returned during create.
set params [java::new {java.lang.Object[]} 1]
$params set 0 false

set sigs [java::new {java.lang.String[]} 1]
$sigs set 0 java.lang.boolean

set taskStatus [java::cast com.ibm.websphere.scheduler.TaskStatus [$AdminControl invoke_jmx $schedO
 cancel $params $sigs]]
```

**Transactionality**. All methods of the Scheduler API are transactional. If a global transactional context is present, it is used to perform the operation. If an unexpected exception is thrown, the transaction is marked to roll back, and the caller must handle it appropriately. If an expected or declared exception is thrown, the transaction remains intact and the caller must choose to roll back or to commit the transaction. If the transaction is rolled back at some point, all scheduler operations performed within the transaction are also rolled back.

If a local transactional context is present, it is suspended and a new global transactional context begins. Likewise, if no transactional context is active, a global transactional context begins. In both cases, if an unexpected exception is thrown, the transaction rolls back. If a declared exception is thrown, the transaction is committed.

If another thread is concurrently modifying the task in question, a TaskPending exception is thrown. This is because schedulers lock the database optimistically. The calling application can then retry the operation.

Task management functions may block if the task is currently running. Because the scheduler guarantees that each task will run only once, the task must be locked for the duration of a running task. Likewise, if a task is changed using one of the management functions but the global transaction is not committed, any other management functions issued from another transaction for that task will be blocked.

A stateless session bean task's TaskHandler.process() method can change it's own state. However, the task must be running within the same transaction as the scheduler. Therefore, a running task can only modify itself if it is using the Required or Mandatory container managed transaction types. If the Requires New transaction type is specified on the process() method, all management functions will deadlock.

All methods defined by the Scheduler API are described in the API documentation.

# Identifying tasks that are currently running

When a task runs, the task database record is locked until the task completes. This topic describes how to determine whether or not a task is running.

## About this task

Prior to version 6.0.2, all tasks ran in a single global transaction. This process not only prevented the task from running more than once successfully, but it also blocked all attempts at reading the state of the task, since each task used read-committed transaction isolation.

There are two methods for determining whether a task is running:

1. **NotificationSink**

   A NotificationSink EJB can be set on the task using the setNotificationSink method on the TaskInfo object. The NotificationSink bean can then log the life cycle of the task to a separate database record in a custom table. This would result in a history log of the task that can be queried independently from the scheduler. This solution works for all versions of the scheduler service. See the Receiving Scheduler Notifications topic for details.
2. **Delayed Execution and Uncommitted Read**

   In Version 6.0.2 and later, two behaviors enable the scheduler find and retrieve API methods, such as getTask, getTaskStatus or findTasksByName, to see the current state of the task without blocking. To see the current state of the task, including its uncommitted running state, complete the following steps:

## Procedure

1. Enable read-uncommitted transaction isolation for the scheduler read methods to prevent these methods from blocking while a task is running. To set the default transaction isolation for read methods, see the Configuring scheduler default transaction isolation topic for read operation details.

   **Important:** If the scheduler database does not support uncommitted reads, such as Oracle, it might not be possible to determine if a task is running unless you use the QOS_ATLEASTONCE quality of service.
2. Use the TaskInfo.EXECUTION_DELAYEDUPDATE option on the TaskInfo.setTaskExecutionOptions method to force the scheduler to write the TaskStatus.RUNNING state to the task when that task starts running.

# Stopping tasks that are failing

The scheduler runs tasks in a global transactional context, by default. If a task is failing due to a configuration problem or application error, the scheduler attempts to retry the task until the scheduler failure threshold is reached. This topic describes how to stop the tasks that are failing.

### Before you begin

The default scheduler failure threshold is `10` and can be configured using the taskFailureThreshold scheduler custom property. To configure this custom property, in the administrative console click **Resources** > **Schedulers** > ***scheduler_name*** and click **Custom Properties**. Valid values are non-negative integers, that is, integers greater than `0`.

### About this task

When the task reaches the failure threshold, the scheduler stops running the task until the scheduler daemon is restarted using the WASScheduler MBean, the scheduler fails over to another server, or until the scheduler is resumed using the resume method on the Scheduler API or WASScheduler MBean.

### Procedure

1. Cancel or suspend a transactional (QOS_ONLYONCE) task that is continually failing. This action can be difficult if the scheduler has not yet reached the failure threshold. The cancel and suspend Scheduler API methods or WASScheduler MBean operations block until the task fails or the method times out, while waiting for a database lock and throws a TaskPending exception. If this occurs, then the application can retry the cancel or suspend operation until it completes.
2. Alternatively, stop the scheduler daemon using the stopDaemon operation on the WASScheduler MBean to avoid running the task multiple times, and run the cancel or suspend operation while it is stopped. While the daemon is stopped, the scheduler does not run tasks. However, all MBean operations and API methods are still available.

## Scheduler tasks and Java EE context

When a task is created using the Scheduler API create() method, the Java Platform, Enterprise Edition (Java EE) thread context of the creator is stored with the scheduled task. When the task runs, the original Java EE thread context is reapplied to the thread before calling the customer TaskInfo instance.

The scheduler service utilizes the asynchronous beans deferred start mechanism to propagate Java EE service context information to a task when it runs. The amount of service context information that is propagated is controlled by the Service Context settings on the WorkManager configuration object that schedulers reference. For example, security and internationalization service contexts can be enabled. See the Using asynchronous beans topic for details on how to configure the Application Server to propagate these service contexts.

### Transactions and schedulers

The scheduler runs a task in a single global transaction, by default. You can use the QOS_ONLYONCE or QOS_ATLEASTONCE quality of service to specify whether the task runs as a single unit of work once or as independent transactions.

#### Transaction behavior when running a task

Because the scheduler runs a task in a single global transaction, by default, the transaction is open until the task completes or fails. The resources involved in that transaction are subject to various timeouts and the thread of the task could be identified as hung if the task runs for a long period of time that can span many minutes or hours.

#### QOS_ONLYONCE

Scheduled tasks execute only one time successfully when using the QOS_ONLYONCE quality of service. This action is accomplished by grouping all of the work done in the task as a single unit of work. When each task fires, the following events occur in a single global transactional context:

1. The context of the application that created the task is applied to the thread.
2. A global transactional context is started.

3. The next fire time and start-by time are calculated using the UserCalendar bean or the DefaultUserCalendar.

   **Important:** If using the TaskInfo.setTaskExcecutionOptions method with the TaskInfo.EXECUTION_DELAYEDUPDATE option, this step will occur after the record is updated.
4. The task database task record is updated in the database with the state of the next task or deleted if the task is complete and the task's auto-purge setting is true.
5. The task database record is updated in the database with the state of the next task or deleted if the task is complete and the task's auto-purge setting is true. If the EXECUTION_DELAYEDUPDATE option is used, the database will not reflect the next state of the task, but the current state with the TaskStatus.RUNNING state set.
6. If the NotificationSink bean is set, a FIRING notification is fired.
7. The BeanTaskInfo or MessageTaskInfo object starts.
8. If the task fails and the NotificationSink bean is set, a FIRE_FAILED notification is fired on a separate transaction.
9. If the task's NotificationSink bean is set, then the various notifications are fired as required.
10. If the EXECUTION_DELAYEDUPDATE option is used for the task, the database will be updated a second time with the next state of the task.
11. The global transaction is committed.

Because all events belonging to a task are executed in a single global transactional context, consider the following points in order to avoid transaction-related errors:

- Each resource participating in the task transaction must be two-phase XA capable.

  This includes the Java Database Connectivity (JDBC) datasource that is configured for the scheduler, any Java Messaging Service (JMS) services used by the MessageTaskInfo objects, and any resources used within any of the UserCalendar, TaskHandler, or NotificationSink beans that have a transaction setting of "Required".
- One resource can be single-phase, if last participant support is enabled for the application that created the transaction. Enable last participant support using an assembly tool. You can also enable last participant support through the administrative console. See the Last participant support extension settings topic for details.

All unexpected exceptions are logged to the activity log and all events participating in the task global transaction are rolled back. This includes changes to the task database record, which force the task to be executed again when the scheduler daemon polls the database during the next poll cycle. The UserCalendar, TaskHandler, and NotificationSink beans can choose not to participate in the global transaction by configuring the bean transaction setting to "Requires new".

## QOS_ATLEASTONCE

Scheduled tasks that use the QOS_ATLEASTONCE quality of service do not have a single transactional context. In this case, each calendar calculation, event notification and database update occurs in an independent transaction:

1. The context of the application that created the task is applied to the thread.
2. The task’s database record is updated with the RUNNING state of the task.
3. UserCalendar, NotificationSink beans are called.
4. The BeanTaskInfo or MessageTaskInfo is started.
5. Result notifications are sent.
6. The database is updated with the next state of the task, if the task has not been changed since the RUNNING state was written.

If a failure happens after the RUNNING state is written to the database and before the result is written, then the task may run more than one time.

When using QOS_ATLEASTONCE, all NotificationSink, UserCalendar and TaskHandler beans must not mandate a transaction (TX_MANDATORY), since there is no global transaction available when the task runs. The EJB components use "Required" or "Requires new" container managed transaction or a bean managed transaction.

### Transaction behavior when using the Scheduler API methods or WASScheduler MBean operations

All Scheduler interface methods participate in a single global transactional context. If a global transactional context is already present on the thread when the create(), suspend(), resume(), cancel(), and purge() methods are executed, then the existing global transaction is used. Otherwise, a new global transaction begins.

If the method participates in the global transaction of the caller and an unexpected error occurs, then the transaction is marked to roll back. If the exception is a declared exception, then the exception is resubmitted to the caller, and the transaction is left alone for the caller to commit or roll back.

If the method starts its own global transaction and any exception occurs, then the transaction is rolled back, and the exception is resubmitted to the caller.

## Scheduler task user authorization

The scheduler service uses the asynchronous beans deferred start mechanism to propagate Java Platform, Enterprise Edition (Java EE) service context information to a task when it runs. If you plan to secure your application using the JAAS security context of the administrative security mechanism built into WebSphere Application Server, create each task with the correct credentials on the thread.

Tasks run with specified security credentials using the following methods:

- Using the Java Authentication and Authorization Service (JAAS) security context on the thread at the time the task was created. See the Deferred start and security topic in the Asynchronous beans section of the information center.
- Using the setAuthenticationAlias method on the TaskInfo object.
- Using a specified security identity on a BeanTaskInfo task TaskHandler EJB method.

The scheduler service utilizes the asynchronous beans deferred start mechanism to propagate Java EE service context information to a task when it runs. The amount of service context information that is propagated is controlled by the Service Context settings on the WorkManager configuration object that schedulers reference. For example, security and internationalization service contexts can be enabled. See the Using asynchronous beans topic for details on how to configure the Application Server to propagate these service contexts.

### Java Authentication and Authorization Service Security context

If you intend to secure your application using the JAAS security context of the administrative security mechanism built into WebSphere Application Server, create each task with the correct credentials on the thread. Once each task has the correct credentials, you can disable and re-enable administrative security without causing any security problems. If you do not set the security context when the scheduler task is created and you later enable security in the target application, a security exception or error message might display, such as SECJ0053E. You might also see this error if two or more schedulers on different servers are accessing the same tables (a clustered or redundant scheduler) and the security settings are different.

The JAAS security context is not set if any of the follow conditions are true:

- Administrative security is disabled.
- Security context policies are disabled on the configured WorkManager for the associated scheduler configuration.

- A credential is not set on the thread. For example, the enterprise bean or servlet that is used to create the scheduled task is not secured, or the task was created with a WASScheduler MBean.

If any of the previously mentioned conditions are true when you create your task and you need to enable security on your application server or application, you must complete the following steps for each task:

1. Find the task using the Scheduler API find or get methods.
2. Cancel the task using the Scheduler.cancel() API.
3. Recreate the task using the Scheduler.create() method with security enabled. Submitting a task that was retrieved from the scheduler using the find or get methods will automatically generate a new task ID.

### Security order of precedence

As previously noted, there are three ways of verifying that a task will run with the correct user credentials. In addition, each TaskInfo implementation may have its own way of supplying user information, which may override the standard mechanisms. If multiple methods are used, refer to the following lists to determine which security mechanism is going to be employed.

BeanTaskInfo

1. TaskHandler security identity set on the process() method of the Enterprise Java Bean file
2. Authentication Alias set with the setAuthenticationAlias method on the TaskInfo interface
3. JAAS security context

MessageTaskInfo

1. Authentication Alias set with the setAuthenticationAlias method on the TaskInfo interface
2. The setUsername and setPassword methods on the MessageTaskInfo interface. See the Deprecated features article for more information.

## Securing scheduler tasks

Scheduled tasks are protected using application isolation and administrative roles. This topic describes how to secure scheduler tasks.

### About this task

If a task is created using a Java Platform, Enterprise Edition (Java EE) server application, only applications with the same name can access those tasks. Tasks created with a WASScheduler MBean using the AdminClient interface or scripting are not part of a J2EE application and have access to all tasks regardless of the application with which they were created. Tasks created with a WASScheduler MBean are only accessible from the WASScheduler MBean API and are not accessible from the Scheduler API.

If the Use Administration Roles attribute is enabled on a scheduler and administrative security is enabled on the Application Server, all Scheduler API methods and WASScheduler MBean API operations enforce access based on the WebSphere Administration Roles. If either of these attributes are disabled, then all API methods are fully accessible by all users.

### Procedure

1. Enable security for all application servers.
2. Manage schedulers.

## Scheduler configuration or topology

The scheduler uses a database to persist information concerning which tasks to run and when. Errors might occur when changing the application server topology or when changing the application or server configuration. When you change the configuration or topology, carefully consider how this action affects the scheduler.

### Restricting security

If you created tasks with an application server while security is disabled, and you later decide to enable security, then the scheduler might have difficulty running tasks. When you create a task, the security context of the application thread is automatically stored with the task. If security is not stored with the task (see Scheduler task user authorization), and you later enable security on the server or application where the task is to run, then the following errors might be logged:

```
SECJ0053E: Authorization failed for /UNAUTHENTICATED while invoking (Home)com/ibm/websphere/scheduler
/TaskHandler create:2 securityName: /UNAUTHENTICATED;accessID: UNAUTHENTICATED is not granted any of
the required roles: MySecurityRole
```

Before you enable security on the server or application, determine if any tasks might be adversely affected. If so, use the Scheduler API or WASScheduler MBean to cancel the tasks and recreate them after you configure security.

### Application server topology changes

The scheduler stores javax.ejb.HomeHandle objects for TaskHandler, NotificationSink and UserCalendar *homes* when the task is created. When you run the task later, these home handles are reinflated and used to access the Enterprise JavaBeans (EJB) component home. When the home handle references an EJB on a single-server environment, the home handles have affinity to that server. When the home handle references an EJB component on a cluster, then the home handles have affinity to the cluster.

If the application server or the Workload Managed (WLM) cluster that a home handle is referencing is not available, then the scheduler fails to run the task, and the following error is logged:

```
SCHD0063E: A task with ID 123 failed to run on Scheduler MyScheduler (sched/MyScheduler) because of
an exception: {cause of failure}
```

If you upgrade the application server to a cluster, or if the Object Request Broker (ORB) ORB_LISTENER_ADDRESS is not set to a fixed port number (see Configuring Inbound Transports), then the task might also fail, since the information stored within the home handle does not have the appropriate information to find the desired server.

### Upgrading to a scheduler cluster

A scheduler cluster (not to be confused with a WLM cluster) is a collection of scheduler configurations on different application servers that share the same Java Naming and Directory Interface (JNDI) name, Java Database Connectivity (JDBC) data source and table prefix. If you upgrade a stand-alone scheduler to a clustered scheduler, then the application and any associated resources that the application requires must be available. If this is not the case, the scheduled task fails to run and error messages might be logged:

```
SCHD0103W: The Scheduler MyScheduler (sched/MyScheduler) was unable to run task 123 because the
application or module is unavailable: MyTaskHandlerEJB
```

To avoid issues with application availability and achieve optimal results, use the same servers in a scheduler cluster as those used in a WLM cluster.

### Reusing scheduler tables

When changing any topology, moving from development to production environments, or making any configuration changes that make the environment more restrictive, you might get optimal results if you use

a different set of scheduler tables. Reusing scheduler tables that have scheduled tasks from previous releases without careful planning might cause problems:

- EJB components running on unexpected application servers.
- Tasks failing to run due to invalid or missing security credentials.
- Tasks failing to run due to invalid or missing Java Platform, Enterprise Edition (Java EE) context information.

Diagnosing such problems is challenging and requires analyzing logs on all servers that have a scheduler installed and configured. When the problem tasks are located, the tasks can be cancelled using the Scheduler APIs, or the tables can be dropped and recreated.

## Scheduler interface

Use the `com.ibm.websphere.scheduler.Scheduler` Java object (in the Java™ Naming and Directory Interface (JNDI) namespace for the scheduler configuration) to find a reference to a scheduler and work with tasks.

A `com.ibm.websphere.scheduler.Scheduler` Java object exists in the JNDI namespace for each scheduler configuration. A reference to a scheduler can be obtained by performing a lookup on the JNDI name; however, the lookup is valid only from the server process where the scheduler instance exists. Once a reference has been obtained, tasks can be created, suspended, cancelled, and so on, if the caller has access to the scheduler instance.

For details, see Interface Scheduler in the API documentation.

**Task creation**
: The task is created in the persistent store using the global transactional context of the caller, if present. See the topic, “Transactions and schedulers” on page 1164, for more details. Since this is a transactional operation, the task cannot be run or modified from another thread until the current transaction commits.

**Task modification**
: Tasks that have been created can be modified with the suspend(), resume(), cancel(), and purge() methods. These methods take a Task Identifier string as a parameter, which is generated by the create() method and can be found in the TaskStatus object. If a task is currently running or being modified by another thread, an operation that attempts to modify the state of the task might block on the attempt. Tasks can only be modified by the same application (EAR file) that was used to create the task.

**Task execution**
: Tasks are run in the thread pool specified by the configuration's work manager. If multiple schedulers are configured to share the same database tables, the scheduler is clustered and the tasks found in the table can be run on any of the schedulers, whether or not they are in the same server, node, or cell.

**Task lookup**
: Tasks can be located using the Name property that was assigned at creation time. This is useful when you need to modify a group of tasks and tracking individual task ID's is not convenient.

### TaskInfo interface

TaskInfo objects contain the information to create a task. Several implementations of this class exist, one for each type of task that can run.

Available TaskInfo implementations include:

**BeanTaskInfo**
: Calls a stateless session bean.

**MessageTaskInfo**
: Sends a Java™ Messaging Service (JMS) message to a queue or publishes a message to a topic. For details, see the Interface TaskInfo in the API documentation.

After a TaskInfo object is created, it can be submitted to the scheduler for task creation by calling the Scheduler.create() method.

For details about the TaskInfo interface, see the API documentation .

## TaskHandler interface

A task handler is a user-defined stateless session bean that is called by tasks created using a BeanTaskInfo object.

A task handler bean uses the following home and remote interfaces, which are defined in the deployment descriptor using an assembly tool, such as Rational Application Developer:

```
com.ibm.websphere.scheduler.TaskHandlerHome
com.ibm.websphere.scheduler.TaskHandler
```

The bean itself needs to implement the process() method defined in the remote interface. For details, see the Interface TaskHandler in the API documentation.

Once an EJB is created and available within an enterprise application, it can be called by a BeanTaskInfo task when it runs. See the Developing a task that calls a session bean topic for details.

When a task is created using a BeanTaskInfo object, the process() method on the TaskHandler session bean is called whenever the task runs. Because the TaskStatus object for the task is passed as a parameter to the process() method, the task handler determines different types of information about the task, such as when it will fire next, the number of repeats remaining, its name and its ID.

The process() method can also change its own state. However, the task must be running within the same transaction as the scheduler. Therefore, a running task can only modify itself if it is using the **Required** or **Mandatory** container managed transaction types. If the **Requires New** transaction type is specified on the process()method, all management functions deadlock.

## NotificationSink interface

A notification sink is a user-defined stateless session bean that is called when the task changes state.

A notification sink bean uses the following home and remote interfaces, which are defined in the deployment descriptor using an assembly tool, such as Rational Application Developer:

```
com.ibm.websphere.scheduler.NotificationSinkHome
com.ibm.websphere.scheduler.NotificationSink
```

The bean itself needs to implement the handleEvent() method defined in the remote interface. For details, see the Interface NotificationSink section of the API documentation and the Receiving scheduler notifications topic.

A NotificationSink provides an event notification callback on a task-by-task basis. A notification sink is set on the TaskInfo interface, using the setNotificationSink() method. If a notification sink is not specified on a task, all notifications are lost; however, the status of a task can be determined by calling the getStatus() method from the Scheduler interface. A notification callback is made for each of the following events:

- Scheduled
- Suspended
- Resumed
- Fired
- Firing
- Fire Failed
- Complete
- Purged

## UserCalendar interface

A user calendar is a user-defined stateless session bean that is called by tasks when they need to calculate date-related values.

A user calendar bean uses the following home and remote interfaces, which are defined in the deployment descriptor using an assembly tool, such as Rational Application Developer:

```
com.ibm.websphere.scheduler.UserCalendarHome
com.ibm.websphere.scheduler.UserCalendar
```

The bean itself needs to implement the applyDelta(), validate(), and getCalendarNames() methods defined in the remote interface. For details, see the Interface UserCalendar in the API documentation.

User calendars are used to calculate time intervals, such as the time between task runs. A user calendar takes a java.util.Date object, applies the interval string and returns the resulting java.util.Date.

User calendars are set with the setUserCalendar() method on the TaskInfo interface and called by the scheduler run-time code when a delta calculation is necessary.

The following methods on the TaskInfo interface specify delta strings that use the user calendar for calculation:

- setStartTimeInterval
- setStartByInterval
- setRepeatInterval

**Default user calendar**

If a user calendar has not been specified using the TaskInfo.setUserCalendar() method, a default user calendar is used. The default calendar allows for simple delta specifications, such as seconds, minutes, hours, days, and months. See the API documentation for details on the default calendar. The default user calendar also provides a CRON-like syntax for calculating absolute times versus time deltas.

**Calendar identifiers**

A single user calendar can contain logic for multiple calendars. A calendar specifier string determines which calendar is used. For example, a calendar bean might be implemented to recognize the interval *day*. However, the identifier also recognizes two calendar implementations: *standard* (for a standard calendar day) and *business* (for a business day).

**Internationalization and time zones**

Scheduler makes use of the java.util.Date class when storing and processing dates. Internally, this class saves the time as milliseconds since the Epoch, Greenwich Mean Time. Since the Date is not converted to local time until converted to a string, the scheduler respects the time zone where the date was created.

**Writing user calendars**

Because the user calendar is a stateless session bean, the same Java Platform, Enterprise Edition (Java EE) programming model available to other session beans is available to the user calendar as well.

# Chapter 26. Developing security

Secure specific types of applications, such as applications that include portlets, SIP servlets, enterprise beans, web services. Find security information that focuses on specific concerns, such as messaging, transaction support, naming and directory, data access.

## Developing extensions to the WebSphere security infrastructure

WebSphere Application Server provides various plug points so that you can extend the security infrastructure. Extending this security infrastructure involves several activities including: Developing custom user registries, developing applications that use programmatic security, and customizing web application login forms.

### About this task

The following topics are covered in this section:

### Procedure

- Developing custom user registries
- Developing applications that use programmatic security
- Customizing web application login forms
- Customizing application login forms with Java Authentication and Authorization Service (JAAS)
- Securing transports with Java Secure Sockets Extension (JSSE) and Java Cryptography Extension (JCE) programming interfaces
- Implementing tokens for security attribute propagation
- Implementing a custom authentication provider using JASPI

## Developing stand-alone custom registries

This development provides considerable flexibility in adapting WebSphere Application Server security to various environments where some notion of a user registry, other than LDAP or Local OS, already exists in the operational environment.

### Before you begin

WebSphere Application Server security supports the use of stand-alone custom registries in addition to the local operating system registry, stand-alone Lightweight Directory Access Protocol (LDAP) registries, and federated repositories for authentication and authorization purposes. A stand-alone custom-implemented registry uses the UserRegistry Java interface as provided by WebSphere Application Server. A stand-alone custom-implemented registry can support virtually any type or notion of an accounts repository from a relational database, flat file, and so on.

Implementing a stand-alone custom registry is a software development effort. Implement the methods that are defined in the com.ibm.websphere.security.UserRegistry interface to make calls to the appropriate registry to obtain user and group information. The interface defines a general set of methods for encapsulating a wide variety of registries. You can configure a stand-alone custom registry as the selected repository when configuring WebSphere Application Server security on the Global security panel.

In WebSphere Application Server Version 8.0, make sure that your implementation of the stand-alone custom registry does not depend on any WebSphere Application Server components such as data sources, Enterprise JavaBeans (EJB) and Java Naming and Directory Interface (JNDI). You can not have this dependency because security is initialized and enabled prior to most of the other WebSphere Application Server components during startup. If your previous implementation used these components,

© Copyright IBM Corp. 2011

make a change that eliminates the dependency. For example, if your previous implementation used data sources to connect to a database, instead use the JDBC java.sql.DriverManager interface to connect to the database.

If your previous implementation uses data sources to connect to a database, change the implementation to use Java database connectivity (JDBC) connections.

## Procedure

1. Implement all the methods in the interface except for the CreateCredential method, which is implemented by WebSphere Application Server.
2. Build your implementation.

   To compile your code, you need the *app_server_root*/plugins/com.ibm.ws.runtime.jar and the *app_server_root*/plugins/com.ibm.ws.security.crypto.jar files in your class path. For example:

   Windows

   ```
   app_server_root/java/bin/javac -classpath
   app_server_root/plugins/com.ibm.ws.runtime.jar;
   app_server_root/plugins/com.ibm.ws.security.crypto.jar your_implementation_file.java
   ```

   AIX HP-UX Linux Solaris

   ```
   app_server_root\java\bin\javac -classpath
   app_server_root\plugins\com.ibm.ws.runtime.jar:
   app_server_root\plugins\com.ibm.ws.security.crypto.jar your_implementation_file.java
   ```
3. Copy the class files that are generated in the previous step to the product class path.

   The preferred location is the following directory:

   - Windows *%install_root%*/lib/ext
   - AIX HP-UX Linux Solaris *%install_root%*\lib\ext

   directory. Copy these class files to all of the product process class paths.
4. To configure your implementation using the administrative console, follow the steps in topics about configuring stand-alone custom registries. This step is required to implement custom user registries.

## Example

Viewing stand-alone custom registries.

Use these links to view registry examples.

A *stand-alone custom registry* is a customer-implemented registry that implements the UserRegistry Java interface, as provided by WebSphere Application Server. A custom-implemented registry can support virtually any type or form of an accounts repository from a relational database, flat file, and so on. The custom registry provides considerable flexibility in adapting WebSphere Application Server security to various environments where some form of a registry, other than a federated repository, Lightweight Directory Access Protocol (LDAP) registry, or local operating system registry, already exist in the operational environment.

## What to do next

If you enable security, make sure that you complete the remaining steps:

1. Save and synchronize the configuration and restart all of the servers.
2. Try accessing some J2EE resources to verify that the custom registry implementation is correct.

## Result.java file

This module is used by user registries in WebSphere Application Server when calling the getUsers and getGroups methods. The user registries use this method to set the list of users and groups and to indicate if more users and groups in the user registry exist than requested.

```
//
//  5639-D57, 5630-A36, 5630-A37, 5724-D18

//
package com.ibm.websphere.security;

import java.util.List;

public class Result implements java.io.Serializable {
    /**
      Default constructor
    */
    public Result() {
    }

    /**
       Returns the list of users and groups
       @return the list of users and groups
    */
    public List getList() {
      return list;
    }

    /**
       indicates if there are more users and groups in the registry
    */
    public boolean hasMore() {
      return more;
    }
    /**
       Set the flag to indicate that there are more users and groups
       in the registry to true
    */
    public void setHasMore() {
      more = true;
    }

    /*
      Set the list of users and groups
      @param list   list of users/groups
    */
    public void setList(List list) {
      this.list = list;
    }

    private boolean more = false;
    private List list;
}
```

## UserRegistry.java files

The following file is a custom property that is used with a custom user registry.

For more information, see Configuring stand-alone custom registries.

```
// 5639-D57, 5630-A36, 5630-A37, 5724-D18
// (C) COPYRIGHT International Business Machines Corp. 1997, 2005

      throws CustomRegistryException,
             RemoteException;
  /**
   * Checks the password of the user. This method is called to authenticate a
   * user when the user's name and password are given.
   *
   * @param userSecurityName the name of the user
   * @param password the password of the user
   * @return a valid userSecurityName. Normally this is
   *   the name of same user whose password was checked but if the
   *  implementation wants to return any other valid
   *  userSecurityName in the registry it can do so
   * @exception CheckPasswordFailedException if userSecurityName/
   *  password combination does not exist in the registry
   * @exception CustomRegistryException if there is any registry specific
   *             problem
   * @exception RemoteException as this extends java.rmi.Remote
   **/
   public String checkPassword(String userSecurityName, String password)
      throws PasswordCheckFailedException,
             CustomRegistryException,
             RemoteException;

  /**
   * Maps a certificate (of X509 format) to a valid user in the registry.
   * This is used to map the name in the certificate supplied by a browser
   * to a valid userSecurityName in the registry
   *
   * @param cert the X509 certificate chain
   * @return the mapped name of the user userSecurityName
   * @exception CertificateMapNotSupportedException if the particular
   *            certificate is not supported.
   * @exception CertificateMapFailedException if the mapping of the
   *            certificate fails.
   * @exception CustomRegistryException if there is any registry specific
   *            problem
   * @exception RemoteException as this extends java.rmi.Remote
   **/
   public String mapCertificate(X509Certificate[] cert)
      throws CertificateMapNotSupportedException,
             CertificateMapFailedException,
             CustomRegistryException,
             RemoteException;

  /**
   * Returns the realm of the registry.
   *
   * @return the realm. The realm is a registry-specific string indicating
   *            the realm or domain for which this registry
   *            applies.  For example, for OS400 or AIX this would be the
   *            host name of the system whose user registry this object
   *            represents.
   *            If null is returned by this method realm defaults to the
   *            value of "customRealm". It is recommended that you use
   *            your own value for realm.
```

```
 * @exception CustomRegistryException if there is any registry specific
 *            problem
 * @exception RemoteException as this extends java.rmi.Remote
 **/

```

# Implementing custom password encryption

WebSphere Application Server supports the use of custom password encryption.

## Before you begin

An installation can implement any password encryption algorithm it chooses.

## About this task

Complete the following steps to implement custom password encryption:

## Procedure

1. Build your custom password encryption class. An example of a custom password encryption class follows.

```
// CustomPasswordEncryption
// Encryption and decryption functions
public interface CustomPasswordEncryption {
    public EncryptedInfo encrypt(byte[] clearText) throws PasswordEncryptException;
    public byte[] decrypt(EncryptedInfo cipherTextInfo) throws PasswordEncryptException;
    public void initialize(HashMap initParameters);
};
// Encapsulation of cipher text and label
public class EncryptedInfo {
    public EncryptedInfo(byte[] bytes, String keyAlias);
    public byte[] getEncryptedBytes();
    public String getKeyAlias();
};
```

2. If you need to custom encode passwords in property files, manually edit the PropFilePasswordEncoder.sh or PropFilePasswordEncoder.bat file.
   a. Use a file editor to open the PropFilePasswordEncoder.sh or PropFilePasswordEncoder.bat file.
   b. Locate the following lines near the end of the file:

```
"%JAVA_HOME%/bin/java" -Dcmd.properties.file=%TMPJAVAPROPFILE%
"-Dwas.install.root=%WAS_HOME%" com.ibm.ws.bootstrap.WSLauncher
com.ibm.ws.security.util.PropFilePasswordEncoder %1 %2
```

   c. Add following lines to the call.

      These custom properties will be passed to the command so that PropFilePasswordEncoder will look for custom encoding classes and utilize it.

```
-Dcom.ibm.wsspi.security.crypto.customPasswordEncryptionEnabled=true
-Dcom.ibm.wsspi.security.crypto.customPasswordEncryptionClass=(customEncoding class file)
```

   The updated lines should look like the following lines:

```
"%JAVA_HOME%/bin/java" -Dcmd.properties.file=%TMPJAVAPROPFILE%
-Dcom.ibm.wsspi.security.crypto.customPasswordEncryptionEnabled=true
-Dcom.ibm.wsspi.security.crypto.customPasswordEncryptionClass=(customEncoding class file)
"-Dwas.install.root=%WAS_HOME%" com.ibm.ws.bootstrap.WSLauncher
com.ibm.ws.security.util.PropFilePasswordEncoder %1 %2
```

3. Enable custom password encryption.
   a. Set the custom property **com.ibm.wsspi.security.crypto.customPasswordEncryptionClass** to the name of the class that is to be given control.
   b. Enable the function. Set the custom property, **com.ibm.wsspi.security.crypto.customPasswordEncryptionEnabled** to `true`.

### Results

Custom password encryption at the installation is complete.

## Developing applications that use programmatic security

For some applications, declarative security is not sufficient to express the security model of the application. Use this topic to develop applications that use programmatic security.

### About this task

IBM WebSphere Application Server provides security components that provide or collaborate with other services to provide authentication, authorization, delegation, and data protection. WebSphere Application Server also supports the security features that are described in the Java Platform, Enterprise Edition (Java EE) specification. An application goes through three stages before it is ready to run:

- Development
- Assembly
- Deployment

Most of the security for an application is configured during the assembly stage. The security that is configured during the assembly stage is called *declarative security* because the security is *declared* or *defined* in the deployment descriptors. The declarative security is enforced by the security runtime. For some applications, declarative security is not sufficient to express the security model of the application. For these applications, you can use *programmatic security*.

### Procedure

1. Develop secure web applications. For more information, see “Developing with programmatic security APIs for web applications” on page 1203.
2. Develop servlet filters for form login processing. For more information, see “Developing servlet filters for form login processing” on page 1217.

3. Develop form login pages. For more information, see “Customizing web application login” on page 1214.
4. Develop enterprise bean component applications. For more information, see “Developing with programmatic APIs for EJB applications” on page 1210.
5. Develop with Java Authentication and Authorization Service to log in programmatically.

   For more information, see topics about developing programmatic logins with the Java Authentication and Authorization Service.
6. Develop your own Java EE security mapping module.

   For more information, see topics about configuring programmatic logins for Java Authentication and Authorization Service.
7. Develop custom user registries. For more information, see “Developing stand-alone custom registries” on page 1173.
8. Develop a custom interceptor for trust associations.

## Protecting system resources and APIs (Java 2 security) for developing applications

Java 2 security is a programming model that is very pervasive and has a huge impact on application development.

### Before you begin

Java 2 security is orthogonal to Java Platform, Enterprise Edition (Java EE) role-based security; you can disable or enable it independently of administrative security.

However, it does provide an extra level of access control protection on top of the Java EE role-based authorization. It particularly addresses the protection of system resources and application programming interfaces (API). Administrators need to consider the benefits against the risks of disabling Java 2 security.

The following recommendations are provided to help enable Java 2 security in a test or production environment:

1. Make sure the application is developed with the Java 2 security programming model. Developers have to know whether or not the APIs that are used in the applications are protected by Java 2 security. It is very important that the required permissions for the APIs used are declared in the policy file (`was.policy`), or the application fails to run when Java 2 security is enabled. Developers can reference the website for Development Kit APIs that are protected by Java 2 security. See the Programming model and decisions section of the Security: Resources for Learning topic to visit this website.
2. Make sure that migrated applications from previous releases are given the required permissions. Because Java 2 security is not supported or partially supported in previous WebSphere Application Server releases, applications developed prior to Version 5 most likely are not using the Java 2 security programming model. No easy way to find out all the required permissions for the application is available. The following are activities you can perform to determine the extra permissions that are required by an application:
   - Code review and code inspection
   - Application documentation review
   - Sandbox testing of migrated enterprise applications with Java 2 security enabled in a preproduction environment. Enable tracing in WebSphere Java 2 security manager to help determine the missing permissions in the application policy file. The trace specification is: `com.ibm.ws.security.core.SecurityManager=all=enabled`.
   - Use the com.ibm.websphere.java2secman.norethrow system property to aid debugging. Do not use this property in a production environment.

The default permission set for applications is the recommended permission set that is defined in the J2EE 1.3 Specification. The default is declared in the *app_server_root*`/profiles/`*profile_name*`/config/cells/`*cell_name*`/nodes/`*node_name*`/app.policy` policy file with permissions defined in the Development Kit

(*JAVA_HOME*/jre/lib/security/java.policy) policy file that grant permissions to everyone. However, applications are denied permissions that are declared in the profiles/*profile_name*/config/cells/*cell_name*/filter.policy file. Permissions that are declared in the *filter.policy* file are filtered for applications during the permission check.

Define the required permissions for an application in a was.policy file and embed the was.policy file in the application enterprise archive (EAR) file as *YOURAPP.ear/META-INF/was.policy*, see "Configuring Java 2 security policy files" on page 1185 for details.

The following steps describe how to enforce Java 2 security on the cell level for WebSphere Application Server, Network Deployment and the server level for WebSphere Application Server, Express

## Procedure

1. Click **Security > Global security**. The Global security panel is displayed.
2. Select the **Use Java 2 security to restrict application access to local resources** option.
3. Click **OK** or **Apply**.
4. Click **Save** to save the changes.
5. Restart the server for the changes to take effect.

## Results

Java 2 security is enabled and enforced for the servers. Java 2 security permission is selected when a Java 2 security protected API is called.

**When to use Java 2 security**

1. Enable protection on system resources, for example when opening or listening to a socket connection, reading or writing to operating system file systems, reading or writing Java virtual machine system properties, and so on.
2. Prevent application code from calling destructive APIs, for example, calling the System.exit method brings down the application server.
3. Prevent application code from obtaining privileged information (passwords) or gaining extra privileges (obtaining server credentials).

## What to do next

The Java 2 security manager is enhanced to dump the Java 2 security permissions that are granted to all classes on the call stack when an application is denied access to a resource. The java.security.AccessControlException exception is created. However, this tracing capability is disabled by default. You can enable this capability by specifying the server trace service with the com.ibm.ws.security.core.SecurityManager=all=enabled trace specification. When the exception is created, the trace dump provides hints to determine whether the application is missing permissions or the product runtime code or the third-party libraries that are used are not properly marked as privileged when accessing Java 2 security-protected resources.

***Using PolicyTool to edit policy files for Java 2 security:***

Use the **PolicyTool** utility to update policy files.

**Before you begin**

Java 2 security uses several policy files to determine the granted permission for each Java program. The Java Development Kit provides the **PolicyTool** tool to edit these policy files. This tool is recommended for editing any policy file to verify the syntax of its contents. Syntax errors in the policy file cause an AccessControlException exception when the application runs, including the server start. Identifying the cause of this exception is not easy because the user might not be familiar with the resource that has an

access violation. Be careful when you edit these policy files.

**Procedure**

1. Start the **PolicyTool**.

   Windows For example, you can enter the following command at a Windows command prompt:

```
%{was.install.root}/java/jre/bin/policytool
```

   The **PolicyTool** window opens. The tool looks for the `java.policy` file in your home directory. If it does not exist, an error message displays.

   Click **OK**.

2. Click **File** > **Open**.
3. Navigate the directory tree in the **Open** window to pick up the policy file that you need to update. After selecting the policy file, click **Open**. The code base entries are listed in the window.
4. Create or modify the code base entry.
   a. Modify the existing code base entry by double-clicking the code base, or click the code base and click **Edit Policy Entry**. The Policy Entry window opens with the permission list defined for the selected code base.
   b. Create a new code base entry by clicking **Add Policy Entry**.

      The Policy Entry window opens. At the code base column, enter the code base information as a URL format.

      For example, you can enter:

```
app_server_root/InstalledApps/testcase.ear
```

      where the *app_server_root* variable represents your installation location.
5. Modify or add the permission specification.
   a. Modify the permission specification by double-clicking the entry that you want to modify, or by selecting the permission and clicking **Edit Permission**. The Permissions window opens with the selected permission information.
   b. Add a new permission by clicking **Add Permission**. The Permissions window opens. In the Permissions window are four rows for Permission, Target Name, Actions, and Signed By.
6. Select the permission from the Permission list. The selected permission displays. After a permission is selected, the Target Name, Actions, and Signed By fields automatically show the valid choices or they enable text input in the right text input area.
   a. Select **Target Name** from the list, or enter the target name in the right text input area.
   b. Select **Actions** from the list.
   c. Input **Signed By** if it is needed.

      **Important:** The Signed By keyword is not supported in the following policy files: `app.policy`, `spi.policy`, `library.policy`, `was.policy`, and `filter.policy` files. However, the Signed By keyword is supported in the following policy files: `#java.policy`, `server.policy`, and `client.policy` files. The Java Authentication and Authorization Service (JAAS) is not supported in the `app.policy`, `spi.policy`, `library.policy`, `was.policy`, and `filter.policy` files. However, the JAAS principal keyword is supported in a JAAS policy file when it is specified by the java.security.auth.policy Java virtual machine (JVM) system property.
7. Click **OK** to close the Permissions window. Modified permission entries of the specified code base display.
8. Click **Done** to close the window. Modified code base entries are listed. Repeat the previous steps until you complete editing.
9. Click **File** > **Save** after you finish editing the file.

### Results

A policy file is updated. If any policy files need editing, use the **PolicyTool** utility. Do not edit the policy file manually. Syntax errors in the policy files can potentially cause application servers or enterprise applications to not start or function incorrectly. For the changes in the updated policy file to take effect, restart the Java processes.

### *Configuring Java 2 security policy files:*

Users can configure Java 2 security policy files so that the required permission is granted for the specified WebSphere Application Server enterprise application.

### Before you begin

Java 2 security uses several policy files to determine the permissions for each Java programs.

See the Java 2 security policy files topic for the list of available policy files that are supported by WebSphere Application Server.

Two types of policy files are supported by WebSphere Application Server: dynamic policy files and static policy files. Static policy files provide the default permissions. Dynamic policy files provide application permissions. Six dynamic policy files are provided:

*Table 147. Dynamic policy files. This table lists the dynamic policy files.*

| Policy file name | Description |
|---|---|
| `app.policy` | Contains default permissions for all of the enterprise applications in the cell.<br>**Note:** Updates to the `app.policy` file only apply to the enterprise applications on the node to which the `app.policy` file belongs. |
| `was.policy` | Contains application-specific permissions for an WebSphere Application Server enterprise application. This file is packaged in an enterprise archive (EAR) file. |
| `ra.xml` | Contains connector application specific permissions for a WebSphere Application Server enterprise application. This file is packaged in a resource adapter archive (RAR) file. |
| `spi.policy` | Contains permissions for Service Provider Interface (SPI) or third-party resources that are embedded in WebSphere Application Server. The default contents grant everything. Update this file carefully when the cell requires more protection against SPI in the cell. This file is applied to all of the SPIs that are defined in the `resources.xml` file. |
| `library.policy` | Contains permissions for the shared library of enterprise applications. |
| `filter.policy` | Contains the list of permissions that require filtering from the `was.policy` file and the `app.policy` file in the cell. This filtering mechanism only applies to the `was.policy` and `app.policy` files. |

In WebSphere Application Server, applications must have the appropriate thread permissions specified in the `was.policy` or `app.policy` file. Without the thread permissions specified, the application cannot manipulate threads and WebSphere Application Server creates a java.security.AccessControlException exception. The `app.policy` file applies to a specified node. If you change the permissions in one `app.policy` file, you must incorporate the new thread policy in the same file on the remaining nodes. Also, if you add the thread permissions to the `app.policy` file, you must restart WebSphere Application Server to enforce the new permissions. However, if you add the permissions to the `was.policy` file for a specific application, you do not need to restart WebSphere Application Server. An administrator must add the following code to a `was.policy` or `app.policy` file for an application to manipulate threads:

```
grant codeBase "file:${application}" {
  permission java.lang.RuntimePermission "stopThread";
  permission java.lang.RuntimePermission "modifyThread";
  permission java.lang.RuntimePermission "modifyThreadGroup";
};
```

**Important:** The Signed By keyword is not supported in the following policy files: app.policy, spi.policy, library.policy, was.policy, and filter.policy files. However, the Signed By keyword is supported in the following policy files:java.policy, server.policy, and client.policy files. The Java Authentication and Authorization Service (JAAS) is not supported in the app.policy, spi.policy, library.policy, was.policy, and filter.policy files. However, the JAAS principal keyword is supported in a JAAS policy file when it is specified by the java.security.auth.policy Java virtual machine (JVM) system property. You can statically set the authorization policy files in java.security.auth.policy with auth.policy.url.n=*URL*, where *URL* is the location of the authorization policy.

**Procedure**

1. Identify the policy file to update.
   - If the permission is required by an application, update the static policy file. Refer to “Configuring static policy files in Java 2 security” on page 1197.
   - If the permission is required by all of the WebSphere Application Server enterprise applications in the node, refer to “spi.policy file permissions” on page 1193.
   - If the permission is required only by specific WebSphere Application Server enterprise applications and the permission is required only by connector, update the ra.xml file. Refer to Refer to the Assembling resource adapter (connector) modules article for more information. Otherwise, update the was.policy file. Refer to “Configuring the was.policy file for Java 2 security” on page 1191 and “Adding the was.policy file to applications for Java 2 security” on page 1195.
   - If the permission is required by shared libraries, refer to “library.policy file permissions” on page 1194.
   - If the permission is required by SPI libraries, refer to “spi.policy file permissions” on page 1193.

   **Tip:** Pick up the policy file with the smallest scope. You can avoid giving an extra permission to the Java programs and protect the resources. You can update the ra.xml file or the was.policy file rather than the app.policy file. Use specific component symbols ($(ejbcomponent), ${webComponent},${connectorComponent} and ${jars}) than ${application} symbols. Update dynamic policy files, rather than static policy files.

   Add any permission that you never want granted to the WebSphere Application Server enterprise application in the cell to the filter.policy file. Refer to “filter.policy file permissions” on page 1189.
2. Restart the WebSphere Application Server enterprise application.

**Results**

The required permission is granted for the specified WebSphere Application Server enterprise application.

**Example**

If an WebSphere Application Server enterprise application in a cell requires permissions, some of the dynamic policy files need updating. The symptom of the missing permission is the java.security.AccessControlException exception. The missing permission is listed in the exception data, which will appear as one line, but is split in sections below for readability.

When a Java program receives this exception and adding this permission is justified, add a permission to an adequate dynamic policy file.

The previous permission information lines are split for the illustration. Enter the permission on one line.

To decide whether to add a permission, refer to the Access control exception for Java 2 security topic.

*app.policy file permissions:*

Java 2 security uses several policy files to determine the granted permissions for each Java program. The union of the permissions that are contained in these following files is applied to the WebSphere Application Server enterprise application. This union determines the granted permissions.

For the list of available policy files that are supported by WebSphere Application Server, see the topic about Java 2 security policy files. The app.policy file is a default policy file that is shared by all of the WebSphere Application Server enterprise applications. The union of the permissions that are contained in the following files is applied to the WebSphere Application Server enterprise application:

- Any policy file that is specified in the policy.url.* properties in the java.security file.
- The app.policy files, which are managed by configuration and file replication services.
- The server.policy file.
- The java.policy file.
- The application was.policy file.
- The permission specification of the ra.xml file.
- The shared library, which is the library.policy file.

In WebSphere Application Server, applications that manipulate threads must have the appropriate thread permissions specified in the was.policy or app.policy file. Without the thread permissions specified, the application cannot manipulate threads and WebSphere Application Server creates a java.security.AccessControlException exception. If an administrator adds thread permissions to the app.policy file, the permission change requires a restart of the WebSphere Application Server. An administrator must add the following code to a was.policy or app.policy file for an application to manipulate threads:

```
grant codeBase "file:${application}" {
  permission java.lang.RuntimePermission "stopThread";
  permission java.lang.RuntimePermission "modifyThread";
  permission java.lang.RuntimePermission "modifyThreadGroup";
};
```

**Important:** The Signed By and the Java Authentication and Authorization Service (JAAS) principal keywords are not supported in the app.policy file. However, the Signed By keyword is supported in the following files: java.policy, server.policy, and the client.policy files. The JAAS principal keyword is supported in a JAAS policy file when it is specified by the java.security.auth.policy Java virtual machine (JVM) system property. You can statically set the authorization policy files in the java.security.auth.policy property with auth.policy.url.n=*URL* where *URL* is the location of the authorization policy.

If the default permissions for enterprise applications (the union of the permissions that is defined in the java.policy file, the server.policy file and the app.policy file) are enough; no action is required. The default app.policy file is used automatically. If a specific change is required to all of the enterprise applications in the cell, update the app.policy file. Syntax errors in the policy files cause start failures in the application servers. Edit these policy files carefully.

**Note:** Updates to the app.policy file only apply to the enterprise applications on the node to which the app.policy file belongs.

To extract the policy file, use a command prompt to enter the following command on one line using the appropriate variable values for your environment:

Windows

```
wsadmin> set obj [$AdminConfig extract cells/cell_name/node/node_name/app.policy c:\temp\test\app.policy]
```

Edit the extracted app.policy file with the Policy Tool. For more information, see “Using PolicyTool to edit policy files for Java 2 security” on page 1183. Changes to the app.policy file are local for the node.

To check in the policy file, use a command prompt to enter the following command on one line using the appropriate variable values for your environment:

Windows

```
wsadmin> $AdminConfig checkin cells/cell_name/nodes/node_name/app.policy c:\temp\test\app.policy $obj
```

*Table 148. Symbols used to associate permission lists to a specific type of resource. Several product-reserved symbols are defined to associate the permission lists to a specific type of resource.*

| Symbol | Meaning |
|---|---|
| file:${application} | Permissions apply to all resources within the application |
| file:${jars} | Permissions apply to all utility Java archive (JAR) files within the application |
| file:${ejbComponent} | Permissions apply to enterprise bean resources within the application |
| file:${webComponent} | Permissions apply to web resources within the application |
| file:${connectorComponent} | Permissions apply to connector resources both within the application and within stand-alone connector resources. |

*Table 149. Symbols provided to specify the path and name for the java.io.FilePermission permission. Five embedded symbols are provided to specify the path and name for the java.io.FilePermission permission. These symbols enable flexible permission specifications. The absolute file path is fixed after the installation of the application.*

| Symbol | Meaning |
|---|---|
| ${app.installed.path} | Path where the application is installed |
| ${was.module.path} | Path where the module is installed |
| ${current.cell.name} | Current cell name |
| ${current.node.name} | Current node name |
| ${current.server.name} | Current server name |

**Tip:** You cannot use the `${was.module.path}` in the `${application}` entry.

**Attention:** In the following code sample, the first two lines that are related to java.io.FilePermission permission are split into two lines for illustrative purposes only.

```
grant codeBase "file:${application}" {
  // The following are required by JavaMail
  permission java.io.FilePermission "${was.install.root}${/}lib${/}activation-impl.jar", "read";
  permission java.io.FilePermission "${was.install.root}${/}lib${/}mail-impl.jar", "read";
};

grant codeBase "file:${jars}" {
  permission java.net.SocketPermission "*", "connect";
  permission java.util.PropertyPermission "*", "read";
};

grant codeBase "file:${connectorComponent}" {
  permission java.net.SocketPermission "*", "connect";
  permission java.util.PropertyPermission "*", "read";
};

grant codeBase "file:${webComponent}" {
  permission java.io.FilePermission "${was.module.path}${/}-", "read, write";
  permission java.lang.RuntimePermission "loadLibrary.*";
  permission java.lang.RuntimePermission "queuePrintJob";
  permission java.net.SocketPermission "*", "connect";
  permission java.util.PropertyPermission "*", "read";
};

grant codeBase "file:${ejbComponent}" {
  permission java.lang.RuntimePermission "queuePrintJob";
  permission java.net.SocketPermission "*", "connect";
  permission java.util.PropertyPermission "*", "read";
};
```

If all of the WebSphere Application Server enterprise applications in a cell require permissions that are not defined as defaults in the `java.policy` file, the `server.policy` file and the `app.policy` file, then update the `app.policy` file. The symptom of a missing permission is the java.security.AccessControlException exception.

**Note:** Updates to the `app.policy` file only apply to the enterprise applications on the node to which the `app.policy` file belongs.

Windows The missing permission is listed in the exception data, for example,

```
java.security.AccessControlException: access denied
(java.io.FilePermission
C:\WebSphere\AppServer\java\jre\lib\ext\mail.jar read)
```

When a Java program receives this exception and adding this permission is justified, add a permission to the `server.policy` file, for example:

Windows

```
grant codeBase "file:user_client_installed_location" {
  permission java.io.FilePermission
"C:\WebSphere\AppServer\java\jre\lib\ext\mail.jar", "read";
 };
```

The previous permission information lines are split for the illustration. You actually enter the permission on one line.

To decide whether to add a permission, refer to the AccessControlException topic.

Restart all WebSphere Application Server enterprise applications to ensure that the updated `app.policy` file takes effect.

*filter.policy file permissions:*

Java 2 security uses several policy files to determine the granted permission for each Java program. Java 2 security policy filtering is only in effect when Java 2 security is enabled.

Before modifying the `filter.policy` file, you must start the wsadmin tool.

Refer to “Protecting system resources and APIs (Java 2 security) for developing applications” on page 1182. The filtering policy defined in the `filter.policy` file is cell wide. The `filter.policy` file is the only policy file that is used when restricting the permission instead of granting permission. The permissions that are listed in the filter policy file are filtered out from the `app.policy` file and the `was.policy` file. Permissions that are defined in the other policy files are not affected by the `filter.policy` file.

When a permission is filtered out, an audit message is logged. However, if the permissions that are defined in the `app.policy` file and the `was.policy` file are compound permissions like the java.security.AllPermission permission, for example, the permission is not removed. A warning message is logged. If the Issue Permission Warning flag is enabled (default) and if the `app.policy` file and the `was.policy` file contain custom permissions (non-Java API permission, the permission package name begins with characters other than `java` or `javax`), a warning message is logged and the permission is not removed. You can change the value of the **Warn if applications are granted custom permissions** option on the Global security panel. It is not recommended that you use the `AllPermission` permission for the enterprise application.

Some default permissions that are defined in the `filter.policy` file. These permissions are the minimal ones that are recommended by the product. If more permissions are added to the `filter.policy` file, certain operations can fail for enterprise applications. Add permissions to the `filter.policy` file carefully.

You cannot use the Policy Tool to edit the `filter.policy` file. Editing must be completed in a text editor. Be careful and verify that no syntax errors exist in the `filter.policy` file. If any syntax errors exist in the `filter.policy` file, the file is not loaded by the product security runtime, which implies that filtering is disabled.

To extract the `filter.policy` file, enter the following command using information from your environment:

set obj [$AdminConfig extract cells/*cell_name*/filter.policy c:/temp/test/filter.policy]

To check in the policy file, enter the following command using information from your environment:

$AdminConfig checkin cells/*cell_name*/filter.policy c:/temp/test/filter.policy $obj

An updated `filter.policy` file is applied to all of the WebSphere Application Server enterprise applications after the servers are restarted. The `filter.policy` file is managed by configuration and file replication services.

The `filter.policy` file that is supplied by WebSphere Application Server resides at: *app_server_root*/`profiles/`*profile_name*`/config/cells/`*cell_name*`/filter.policy`.

This fill contains these permissions as defaults:

```
filterMask {
permission java.lang.RuntimePermission "exitVM";
permission java.lang.RuntimePermission "setSecurityManager";
permission java.security.SecurityPermission "setPolicy";
permission javax.security.auth.AuthPermission "setLoginConfiguration"; };
runtimeFilterMask {
permission java.lang.RuntimePermission "exitVM";
permission java.lang.RuntimePermission "setSecurityManager";
permission java.security.SecurityPermission "setPolicy";
permission javax.security.auth.AuthPermission "setLoginConfiguration"; };
```

The permissions that are defined in `filterMask` filter are for static policy filtering. The security runtime tries to remove the permissions from applications during application startup. Compound permissions are not removed, but are issued with a warning, and application deployment is stopped if applications contain permissions that are defined in the `filterMask` filter, and if scripting is used. The runtimeFilterMask filter defines permissions that are used by the security runtime to deny access to those permissions to application thread. Do not add more permissions to the runtimeFilterMask filter. Application start failure or incorrect functioning might result. Be careful when adding more permissions to the runtimeFilterMask filter. Usually, you only need to add permissions to the `filterMask` stanza.

WebSphere Application Server relies on the filter policy file to restrict or disallow certain permissions that can compromise the integrity of the system. For instance, WebSphere Application Server considers the exitVM and setSecurityManager permissions as those permissions that most applications never have. If these permissions are granted, the following scenarios are possible:

**exitVM**
A servlet, JavaServer Pages (JSP) file, enterprise bean, or other library that is used by the aforementioned might call the System.exit API and cause the entire WebSphere Application Server process to terminate.

**setSecurityManager**
An application might install its own security manager and either grant more permissions or bypass the default policy that the WebSphere Application Server security manager enforces.

**Important:** In application code, do not use the setSecurityManager permission to set a security manager. When an application uses the setSecurityManager permission, a conflict exists with the internal security manager within WebSphere Application Server. If you must set a security manager in an application for Remote Method Invocation (RMI) purposes, you also must select the **Use Java 2 security to restrict application access to local resources** option on the Global security panel within the WebSphere Application Server administrative console.

WebSphere Application Server then registers a security manager, which the application code can verify is registered by using the System.getSecurityManager application programming interface (API).

For the updated `filter.policy` file to take effect, restart related Java processes.

*Configuring the was.policy file for Java 2 security:*

You should update the `was.policy` file if the application has specific resources to access.

**Before you begin**

Java 2 security uses several policy files to determine the granted permission for each Java program. The `was.policy` file is an application-specific policy file for WebSphere Application Server enterprise applications. This file is embedded in the `META-INF/was.policy` enterprise archive (.EAR) file. The `was.policy` file is located in:

*profile_root*/config/cells/*cell_name*/applications/
*ear_file_name*/deployments/*application_name*/META-INF/was.policy

See Java 2 security policy files for the list of available policy files that are supported by WebSphere Application Server Version 6.1.

The union of the permissions that are contained in the following files is applied to the WebSphere Application Server enterprise application:

- Any policy file that is specified in the policy.url.* properties in the `java.security` file.
- The `app.policy` files, which are managed by configuration and file replication services.
- The `server.policy` file.
- The `java.policy` file.
- The application `was.policy` file.
- The permission specification of the `ra.xml` file.
- The shared library, which is the `library.policy` file.

*Table 150. Symbols defined to associate permission lists to a specific type of resource. Several product-reserved symbols are defined to associate the permission lists to a specific type of resource.*

| Symbol | Definition |
|---|---|
| file:${application} | Permissions apply to all resources used within the application. |
| file:${jars} | Permissions apply to all utility Java archive (JAR) files within the application |
| file:${ejbComponent} | Permissions apply to enterprise bean resources within the application |
| file:${webComponent} | Permissions apply to web resources within the application |
| file:${connectorComponent} | Permissions apply to connector resources within the application |

In WebSphere Application Server, applications that manipulate threads must have the appropriate thread permissions specified in the `was.policy` or `app.policy` file. Without the thread permissions specified, the application cannot manipulate threads and WebSphere Application Server creates a java.security.AccessControlException exception. If you add the permissions to the `was.policy` file for a specific application, you do not need to restart WebSphere Application Server. An administrator must add the following code to a `was.policy` or `app.policy` file for an application to manipulate threads:

```
grant codeBase "file:${application}" {
  permission java.lang.RuntimePermission "stopThread";
  permission java.lang.RuntimePermission "modifyThread";
  permission java.lang.RuntimePermission "modifyThreadGroup";
};
```

An administrator can add the thread permissions to the `app.policy` file, but the permission change requires a restart of WebSphere Application Server.

**Important:** The Signed By and the Java Authentication and Authorization Service (JAAS) principal keywords are not supported in the `was.policy` file. The Signed By keyword is supported in the `java.policy`, `server.policy`, and `client.policy` policy file. The JAAS principal keyword is supported in a JAAS policy file when it is specified by the `java.security.auth.policy` Java virtual machine (JVM) system property. You can statically set the authorization policy files in the `java.security.auth.policy` file with the `auth.policy.url.n=`*URL*, where *URL* is the location of the authorization policy.

Other than these blocks, you can specify the module name for granular settings. For example,

```
grant codeBase "file:DefaultWebApplication.war" {
  permission java.security.SecurityPermission "printIdentity";
};

grant codeBase "file:IncCMP11.jar" {
  permission java.io.FilePermission
      "${user.install.root}${/}bin${/}DefaultDB${/}-",
      "read,write,delete";
};
```

*Table 151. Embedded symbols provided to specify the path and name for the java.io.FilePermission permission. Five embedded symbols are provided to specify the path and name for the java.io.FilePermission permission. These symbols enable flexible permission specification. The absolute file path is fixed after the application is installed.*

| Symbol | Definition |
|---|---|
| ${app.installed.path} | Path where the application is installed |
| ${was.module.path} | Path where the module is installed |
| ${current.cell.name} | Current® cell name |
| ${current.node.name} | Current node name |
| ${current.server.name} | Current server name |

### About this task

If the default permissions for the enterprise application are enough, an action is not required. The default permissions are a union of the permissions that are defined in the `java.policy` file, the `server.policy` file, and the `app.policy` file. If an application has specific resources to access, update the `was.policy` file. The first two steps assume that you are creating a new policy file.

**Tip:** Syntax errors in the policy files cause the application server to fail. Use care when editing these policy files.

### Procedure

1. Create or edit a new `was.policy` file by using the PolicyTool. For more information, see “Using PolicyTool to edit policy files for Java 2 security” on page 1183.
2. Package the `was.policy` file into the enterprise archive (EAR) file.

   For more information, see “Adding the was.policy file to applications for Java 2 security” on page 1195.The following instructions describe how to import a `was.policy` file.

   a. Import the EAR file into an assembly tool.

   b. Open the Project Navigator view.

   c. Expand the EAR file and click **META-INF**. You might find a `was.policy` file in the META-INF directory. If you want to delete the file, right-click the file name and select **Delete**.

   d. At the bottom of the Project Navigator view, click **J2EE Hierarchy**.

   e. Import the `was.policy` file by right-clicking the **Modules** directory within the deployment descriptor and by clicking **Import > Import > File system**.

   f. Click **Next**.

   g. Enter the path name to the `was.policy` file in the **From directory** field or click **Browse** to locate the file.

h. Verify that the path directory that is listed in the **Into directory** field lists the correct `META-INF` directory.
i. Click **Finish**.
j. To validate the EAR file, right-click the EAR file, which contains the Modules directory, and click **Run Validation**.
k. To save the new EAR file, right-click the EAR file, and click **Export > Export EAR file**. If you do not save the revised EAR file, the EAR file will contain the new `was.policy` file. However, if the workspace becomes corrupted, you might lose the revised EAR file.
l. To generate deployment code, right-click the EAR file and click **Generate Deployment Code**.

3. Update an existing installed application, if one already exists. Modify the `was.policy` file with the Policy Tool. For more information, see "Using PolicyTool to edit policy files for Java 2 security" on page 1183.

**Results**

The updated `was.policy` file is applied to the application after the application restarts.

**Example**

When a Java program receives this exception and adding this permission is justified, add the following permission to the `was.policy` file:

To determine whether to add a permission, see Access control exception for Java 2 security.

**What to do next**

Restart all applications for the updated `app.policy` file to take effect.

*spi.policy file permissions:*

Java 2 security uses several policy files to determine the granted permission for each Java program.

For the list of available policy files that are supported by WebSphere Application Server Version 6.0.x, see Java 2 security policy files.

Because the default permission for the Service Provider Interface (SPI) is the AllPermission permission, the only reason to update the `spi.policy` file is a restricted SPI permission. When a change in the `spi.policy` is required, complete the following steps.

Syntax errors in the policy files cause the application server to fail. Edit these policy files carefully.

**Important:** Do not place the codebase keyword or any other keyword after the filterMask and runtimeFilterMask keywords. The Signed By and the Java Authentication and Authorization Service (JAAS) Principal keywords are not supported in the `spi.policy` file. The Signed By keyword is supported in the `java.policy`, `server.policy`, and `client.policy` policy files. The JAAS Principal keyword is supported in a JAAS policy file that is specified by the java.security.auth.policy Java virtual machine (JVM) system property. You can statically set the authorization policy files in `java.security.auth.policy` with `auth.policy.url.n=`*`URL`*`,` where *`URL`* is the location of the authorization policy.

To extract the `filter.policy` file, enter the following command using information from your environment:

```
set obj [$AdminConfig extract profiles/profile_name/cells/cell_name/nodes/node_name/spi.policy
  c:/temp/test/spi.policy]
```

Edit the file using the Policy Tool. For more information, see “Using PolicyTool to edit policy files for Java 2 security” on page 1183.

To check in the policy file, enter the following command using information from your environment:

The updated `spi.policy` is applied to the Service Provider Interface (SPI) libraries after the Java process is restarted.

$AdminConfig checkin profiles/*profile_name*/cells/*cell_name*/nodes/*node_name*/spi.policy
c:/temp/test/spi.policy $obj

**Examples**

The `spi.policy` file is the template for SPIs or third-party resources embedded in the product. Examples of SPIs are Java Message Services (JMS) (MQSeries) and Java database connectivity (JDBC) drivers. They are specified in the `resources.xml` file. The dynamic policy grants the permissions that are defined in the `spi.policy` file to the class paths defined in the `resources.xml` file. The union of the permission that is contained in the `java.policy` file and the `spi.policy` file are applied to the SPI libraries. The `spi.policy` files are managed by configuration and file replication services.

You can find the `spi.policy` file that is supplied by WebSphere Application Server in the following location: *app_server_root*/`profiles`/*profile_name*/`config/cells`/*cell_name*/`nodes`/*node_name*/`spi.policy`. This file contains the following default permission:

```
grant {
  permission java.security.AllPermission;
};
```

Restart the related Java processes for the changes in the `spi.policy` file to become effective.

*library.policy file permissions:*

Java 2 security uses several policy files to determine the granted permission for each Java program.

For the list of available policy files that are supported by WebSphere Application Server, see Java 2 security policy files.

The `library.policy` file is the template for shared libraries (Java library classes). Multiple enterprise applications can define and use shared libraries. Refer to Managing shared libraries for information on how to define and manage the shared libraries.

If the default permissions for a shared library (union of the permissions defined in the `java.policy` file, the `app.policy` file and the `library.policy` file) are enough, no action is required. The default library policy is picked up automatically. If a specific change is required to share a library in the cell, update the `library.policy` file.

Syntax errors in the policy files cause the application server to fail. Edit these policy files carefully.

**Important:** Do not place the codebase keyword or any other keyword after the grant keyword. The Signed By keyword and the Java Authentication and Authorization Service (JAAS) Principal keyword are not supported in the `library.policy` file. The Signed By keyword is supported in the `java.policy`, the `server.policy`, and the `client.policy` policy files. The JAAS Principal keyword is supported in a JAAS policy file when it is specified by the Java virtual machine (JVM) system property, java.security.auth.policy. You can statically set the authorization policy files in the `java.security.auth.policy` file with `auth.policy.url.n=`*URL* `where` *URL* is the location of the authorization policy.

To extract the policy file, use a command prompt to enter the following command using the appropriate variable values for your environment:The previous two lines were split onto two lines for illustrative purposes only.

wsadmin> set obj [$AdminConfig extract cells/*cell_name*/nodes/
*node_name*/library.policy c:/temp/test/library.policy]

Edit the extracted `library.policy` file with the Policy Tool. For more information, see “Using PolicyTool to edit policy files for Java 2 security” on page 1183.

To check in the policy file, use a command prompt to enter the following command using the appropriate variable values for your environment:An updated `library.policy` is applied to shared libraries after the servers restart.

wsadmin> $AdminConfig checkin cells/*cell_name*/nodes/*node_name*/library.policy
c:/temp/test/library.policy $obj

**Example**

The union of the permission that is contained in the `java.policy` file, the `app.policy` file, and the `library.policy` file are applied to the shared libraries. The `library.policy` file is managed by configuration and file replication services.

The `library.policy` file are supplied by WebSphere Application Server resides at: *app_server_root*/`config/cells/`*`cell_name`*`/nodes/`*`node_name`*`/` directory. The file contains an empty permission entry as a default. For example:

```
grant {
  };
```

If the shared library in a cell requires permissions that are not defined as defaults in the `java.policy` file, the `app.policy` file and the `library.policy` file, update the `library.policy` file. The missing permission causes the java.security.AccessControlException exception. The missing permission is listed in the exception data.

Windows For example:

```
java.security.AccessControlException: access denied (java.io.FilePermission
app_server_root/lib/mail-impl.jar read)
```

The previous lines are split into two lines for illustrative purposes only. The *app_server_root* variable represents your installation directory.

When a Java program receives this exception and adding this permission is justified, add a permission to the `library.policy` file.

Windows For example:

```
grant { permission java.io.FilePermission "app_server_root/lib/mail-impl.jar", "read"; };
```

The previous lines are split into two lines for illustrative purposes only. The *app_server_root* variable represents your installation directory.

To decide whether to add a permission, refer to Access control exception for Java 2 security.

Restart the related Java processes for the changes in the `library.policy` file to become effective.

*Adding the was.policy file to applications for Java 2 security:*

An application might need a was.policy file if it accesses resources that require more permissions than those granted in the default app.policy file.

**About this task**

When Java 2 security is enabled for a WebSphere Application Server, all the applications that run on WebSphere Application Server undergo a security check before accessing system resources. An application might need a was.policy file if it accesses resources that require more permissions than those granted in the default app.policy file. By default, the product security reads an app.policy file that is located in each node and grants the permissions in the app.policy file to all the applications. Include any additional required permissions in the was.policy file. The was.policy file is only required if an application requires additional permissions.

The default policy file for all applications is specified in the app.policy file. This file is provided by the product security, is common to all applications, and you do not change this file. Add any new permissions that are required for an application in the was.policy file.

The app.policy file supplied by WebSphere Application Server resides at *app_server_root*/config/cells/profile/profile_name/config/*cell_name*/nodes/*node_name*/app.policy. The contents of the app.policy file are presented in the following example:

**Attention:** In the following code sample, the two permissions that are required by JavaMail are split onto two lines for illustration only. You actually enter the permission on one line.

```
// The following permissions apply to all the components under the application.

grant codeBase "file:${application}" {
   // The following are required by JavaMail

  permission java.io.FilePermission "
        ${was.install.root}${/}lib${/}activation-impl.jar",
"read";

  permission java.io.FilePermission "
        ${was.install.root}${/}lib${/}mail-impl.jar","read";

  };
   // The following permissions apply to all utility .jar files  (other
   //  than enterprise beans JAR files) in the application.
grant codeBase "file:${jars}" {
  permission java.net.SocketPermission "*", "connect";
  permission java.util.PropertyPermission "*", "read";
};

// The following permissions apply to connector resources within the application
grant codeBase "file:${connectorComponent}" {
  permission java.net.SocketPermission "*", "connect";
  permission java.util.PropertyPermission "*", "read";
};

// The following permissions apply to all the web modules (.war files)
// within the application.
grant codeBase "file:${webComponent}" {
  permission java.io.FilePermission "${was.module.path}${/}-", "read, write";
       //  where "was.module.path" is the path where the web module is
       //  installed. Refer to Dynamic policy concepts for other symbols.
  permission java.lang.RuntimePermission "loadLibrary.*";
  permission java.lang.RuntimePermission "queuePrintJob";
  permission java.net.SocketPermission "*", "connect";
  permission java.util.PropertyPermission "*", "read";
};

// The following permissions apply to all the EJB modules within the application.
grant codeBase "file:${ejbComponent}" {
 permission java.lang.RuntimePermission "queuePrintJob";
 permission java.net.SocketPermission "*", "connect";
 permission java.util.PropertyPermission "*", "read";
};
```

If additional permissions are required for an application or for one or more modules of an application, use the was.policy file for that application. For example, use codeBase of ${application} and add required permissions to grant additional permissions to the entire application. Similarly, use codeBase of

${webComponent} and ${ejbComponent} to grant additional permissions to all the web modules and all the enterprise bean modules in the application. You can assign additional permissions to each module (.war file or .jar file), as shown in the following example.

This example illustrates adding extra permissions for an application in the was.policy file:

**Attention:** In the following code sample, the permission for the EJB module was split onto two lines for illustration only. You actually enter the permission on one line.

```
// grant additional permissions to a web module
grant codeBase " file:aWebModule.war" {
 permission java.security.SecurityPermission "printIdentity";
};

// grant additional permission to an EJB module
grant codeBase "file:aEJBModule.jar"  {
    permission java.io.FilePermission "
       ${user.install.root}${/}bin${/}DefaultDB${/}-", "read,write,delete";
    // where, ${user.install.root} is the system property whose value is
    // located in the app_server_root directory.
 };
```

To use a was.policy file for your application, perform the following steps:

**Procedure**

1. Create a was.policy file using the policy tool. For more information on using the policy tool, see “Using PolicyTool to edit policy files for Java 2 security” on page 1183.
2. Add the required permissions in the was.policy file using the policy tool.
3. Place the was.policy file in the application enterprise archive (EAR) file under the META-INF directory. Update the application EAR file with the newly created was.policy file by using the **jar** command.
4. Verify that the was.policy file is inserted and start an assembly tool.
5. Verify that the was.policy file in the application is syntactically correct. In an assembly tool, right-click the enterprise application module and click **Run Validation**.

**Results**

An application EAR file is now ready to run when Java 2 security is enabled.

**Example**

This step is required for applications to run properly when Java 2 security is enabled. If the was.policy file is not created and it does not contain required permissions, the application might not access system resources.

The symptom of the missing permissions is the java.security.AccessControlException exception. The missing permission is listed in the exception data, for example,

When an application program receives this exception and adding this permission is justified, include the permission in the was.policy file, for example,

The previous permission information lines are split for the illustration. Enter the permission on one line.

**What to do next**

Install the application.

***Configuring static policy files in Java 2 security:***

By configuring the static policy files, the required permission will be granted for all of the Java programs.

### Before you begin

Java 2 security uses several policy files to determine the granted permission for each Java program.

See the topic about Java 2 security policy files for the list of available policy files that are supported by WebSphere Application Server.

Two types of policy files are supported by WebSphere Application Server: dynamic policy files and static policy files. Static policy files provide the default permissions. Dynamic policy files provide application permissions.

*Table 152. Policy Files. This table lists the policy files.*

| Policy file name | Description |
|---|---|
| `java.policy` | Contains default permissions for all of the Java programs on the node. This file seldom changes. |
| `server.policy` | Contains default permissions for all of the WebSphere Application Server programs on the node. This file is rarely updated. |
| `client.policy` | Contains default permissions for all of the applets and client containers on the node. |

The static policy file is not a configuration file that is managed by the repository and the file replication service. Changes to this file are local and do not get replicated to the other machine.

### Procedure

1. Identify the policy file to update.
   - If the permission is required only by an application, update the dynamic policy file. Refer to "Configuring Java 2 security policy files" on page 1185.
   - If the permission is required only by applets and client containers, update the `client.policy` file. Refer to "client.policy file permissions" on page 1201.
   - If the permission is required only by WebSphere Application Server (servers, agents, managers and application servers), update the `server.policy` file. Refer to "server.policy file permissions" on page 1200.
   - If the permission is required by all of the Java programs running on the Java virtual machine (JVM), update the `java.policy` file. Refer to "java.policy file permissions" on page 1199.
2. Stop and restart WebSphere Application Server.

### Results

The required permission is granted for all of the Java programs that run with the restarted JVM.

### Example

If Java programs on a node require permissions, the policy file needs updating. If the Java program that required the permission is not part of an enterprise application, update the static policy file. The missing permission results in the creation of the java.security.AccessControlException exception. The missing permission is listed in the exception data.

For example:

```
java.security.AccessControlException: access denied (java.io.FilePermission
C:/WAS_HOME/lib/mail-impl.jar read)
```

When a Java program receives this exception and adding this permission is justified, add a permission to an adequate policy file.

For example:

```
grant codeBase "file:user_client_installed_location" {
  permission java.io.FilePermission
  "C:/WAS_HOME/lib/mail-impl.jar",
  "read";
};
```

To decide whether to add a permission, refer to Access control exception for Java 2 security.

*java.policy file permissions:*

Java 2 security uses several policy files to determine the granted permission for each Java program.

See Java 2 security policy files for the list of available policy files that are supported by WebSphere Application Server.

The `java.policy` file is a global default policy file that is shared by all of the Java programs that run in the Java virtual machine (JVM) on the node. A change to the `java.policy` file is local for the node. The default Java policy is picked up automatically. Syntax errors in the policy files cause the application server to fail. An updated `java.policy` file is applied to all the Java programs that run in all the JVMs on the local node. Restart the programs for the updates to take effect. Modifying this file is not recommended. If a specific change is required to some of the Java programs on a node and the `java.policy` file requires updating, carefully modify the `java.policy` file with the policy tool. For more information, see "Using PolicyTool to edit policy files for Java 2 security" on page 1183.

**Default permissions for the `java.policy` file**

The `java.policy` file is not a configuration file that is managed by the repository and the file replication service. Changes to this file are local and do not get replicated to the other machine. The `java.policy` file that is supplied by WebSphere Application Server is located at *install_root*`/java/jre/lib/security/java.policy`. This file contains these default permissions.

```
// Standard extensions get all permissions by default
grant codeBase "file:${java.home}/lib/ext/*" {
        permission java.security.AllPermission;
};
// default permissions granted to all domains
grant {
        // Allows any thread to stop itself using the java.lang.Thread.stop()
        // method that takes no argument.
        // Note that this permission is granted by default only to remain
        // backwards compatible.
        // It is strongly recommended that you either remove this permission
        // from this policy file or further restrict it to code sources
        // that you specify, because Thread.stop() is potentially unsafe.
        // See "http://java.sun.com/notes" for more information.
        // permission java.lang.RuntimePermission "stopThread";

        // allows anyone to listen on un-privileged ports
        permission java.net.SocketPermission "localhost:1024-", "listen";

        // "standard" properties that can be read by anyone

        permission java.util.PropertyPermission "java.version", "read";
        permission java.util.PropertyPermission "java.vendor", "read";
        permission java.util.PropertyPermission "java.vendor.url", "read";
        permission java.util.PropertyPermission "java.class.version", "read";
        permission java.util.PropertyPermission "os.name", "read";
        permission java.util.PropertyPermission "os.version", "read";
        permission java.util.PropertyPermission "os.arch", "read";
        permission java.util.PropertyPermission "file.separator", "read";
        permission java.util.PropertyPermission "path.separator", "read";
        permission java.util.PropertyPermission "line.separator", "read";

        permission java.util.PropertyPermission "java.specification.version", "read";
        permission java.util.PropertyPermission "java.specification.vendor", "read";
        permission java.util.PropertyPermission "java.specification.name", "read";

        permission java.util.PropertyPermission "java.vm.specification.version","read";
        permission java.util.PropertyPermission "java.vm.specification.vendor","read";
        permission java.util.PropertyPermission "java.vm.specification.name", "read";
        permission java.util.PropertyPermission "java.vm.version", "read";
        permission java.util.PropertyPermission "java.vm.vendor", "read";
        permission java.util.PropertyPermission "java.vm.name", "read";
       };
```

If some Java programs on a node require permissions that are not defined as defaults in the `java.policy` file, consider updating the `java.policy` file. Most of the time, other policy files are updated instead of the `java.policy` file. The missing permission causes the creation of the , java.security.AccessControlException exception. The missing permission is listed in the exception data.

For example:

```
java.security.AccessControlException: access denied (java.io.FilePermission
C:\WebSphere\AppServer\java\jre\lib\ext\mail.jar read)
```

The previous two lines are one continuous line.

When a Java program receives this exception and adding this permission is justified, add a permission to the `java.policy` file.

For example:

```
grant codeBase "file:user_client_installed_location" {
permission java.io.FilePermission
"C:\WebSphere\AppServer\java\jre\lib\ext\mail.jar", "read"; };
```

To decide whether to add a permission, refer to Access control exception for Java 2 security.

Restart all of the Java processes for the updated `java.policy` file to take effect.

*server.policy file permissions:*

Java 2 security uses several policy files to determine the granted permission for each Java program.

See Java 2 security policy files for the list of available policy files that are supported by WebSphere Application Server.

The `server.policy` file is a default policy file that is shared by all of the WebSphere Application Servers on a node. The `server.policy` file is not a configuration file that is managed by the repository and the file replication service. Changes to this file are local and do not replicate to the other machine.

If the default permissions for a server (the union of the permissions that is defined in the `java.policy` file and the `server.policy` file) are enough, no action is required. The default server policy is picked up automatically. If a specific change is required to some of the server programs on a node, update the `server.policy` file with the Policy Tool. Refer to the “Using PolicyTool to edit policy files for Java 2 security” on page 1183 topic to edit policy files. Changes to the `server.policy` file are local for the node. Syntax errors in the policy files cause the application server to fail. Edit these policy files carefully. An updated `server.policy` file is applied to all the server programs on the local node. Restart the servers for the updates to take effect.

If you want to add permissions to an application, use the `app.policy` file and the `was.policy` file.

**Note:** Updates to the `app.policy` file only apply to the enterprise applications on the node to which the `app.policy` file belongs.

When you do need to modify the `server.policy` file, locate this file at: *profile_root*`/properties/server.policy`. This file contains these default permissions:

```
// Allow to use sun tools
grant codeBase "file:${java.home}/../lib/tools.jar" {
  permission java.security.AllPermission;
};

// WebSphere system classes
grant codeBase "file:${was.install.root}/plugins/-" {
  permission java.security.AllPermission;
};
grant codeBase "file:${was.install.root}/lib/-" {
  permission java.security.AllPermission;
};
grant codeBase "file:${was.install.root}/classes/-" {
  permission java.security.AllPermission;
};
```

```
// Allow the WebSphere deploy tool all permissions
grant codeBase "file:${was.install.root}/deploytool/-" {
  permission java.security.AllPermission;
};

// Allow Channel Framework classes all permission
grant codeBase "file:${was.install.root}/installedChannels/-" {
  permission java.security.AllPermission;
};

// WebSphere optional runtime classes
grant codeBase "file:${was.install.root}/optionalLibraries/-" {
  permission java.security.AllPermission;
};
```

If some server programs on a node require permissions that are not defined as defaults in the `server.policy` file and the `server.policy` file, update the `server.policy` file. The missing permission creates the java.security.AccessControlException exception. The missing permission is listed in the exception data.

For example:

```
java.security.AccessControlException: access denied (java.io.FilePermission
C:\WebSphere\AppServer\java\jre\lib\ext\mail-impl.jar read)
```

The previous two lines are split into two lines for illustrative purposes only.

When a Java program receives this exception and adding this permission is justified, add a permission to the `server.policy` file.

For example:

```
grant codeBase "file:user_client_installed_location" {
permission java.io.FilePermission
"C:\WebSphere\AppServer\java\jre\lib\ext\mail.jar", "read"; };
```

To decide whether to add a permission, refer to Access control exception for Java 2 security.

Restart all of the Java processes for the updated `server.policy` file to take effect.

*client.policy file permissions:*

Java 2 security uses several policy files to determine the granted permission for each Java program.

For the list of available policy files that are supported by WebSphere Application Server, see Java 2 security policy files.

- The `client.policy` file is a default policy file that is shared by all of the WebSphere Application Server client containers and applets on a node.
- The union of the permissions that is contained in the `java.policy` file and the `client.policy` file are given to all of the client containers for WebSphere Application Server and applets running on the node.
- The `client.policy` file is not a configuration file that is managed by the repository and the file replication service. Changes to this file are local and do not replicate to the other machine.
- The `client.policy` file supplied by WebSphere Application Server is located in the *profile_root*`/properties/client.policy`.
- If the default permissions for a client (union of the permissions defined in the `java.policy` file and the `client.policy` file) are enough, no action is required. The default client policy is picked up automatically.
- If a specific change is required to some of the client containers and applets on a node, modify the `client.policy` file with the Policy Tool. Refer to “Using PolicyTool to edit policy files for Java 2 security” on page 1183, to edit policy files. Changes to the `client.policy` file are local for the node.

This file contains these default permissions:

```
grant codeBase "file:${was.install.root}/java/ext/*" {
  permission java.security.AllPermission;
};

// JDK classes
grant codeBase "file:${was.install.root}/java/ext/-" {
  permission java.security.AllPermission;
};
grant codeBase "file:${was.install.root}/java/tools/ibmtools.jar" {
  permission java.security.AllPermission;
};
grant codeBase "file:/QIBM/ProdData/Java400/jdk14/lib/tools.jar" {
  permission java.security.AllPermission;
};

// WebSphere system classes
grant codeBase "file:${was.install.root}/lib/-" {
  permission java.security.AllPermission;
};
grant codeBase "file:${was.install.root}/plugins/-" {
  permission java.security.AllPermission;
};
grant codeBase "file:${was.install.root}/classes/-" {
  permission java.security.AllPermission;
};
grant codeBase "file:${was.install.root}/installedConnectors/-" {
  permission java.security.AllPermission;
};
grant codeBase "file:${user.install.root}/installedConnectors/-" {
  permission java.security.AllPermission;
};

grant codeBase "file:${was.install.root}/installedChannels/-" {
  permission java.security.AllPermission;
};

// J2EE 1.4 permissions for client container WebSphere Application Server applications
// in $WAS_HOME/installedApps
grant codeBase "file:${user.install.root}/installedApps/-" {
  //Application client permissions
  permission java.awt.AWTPermission "accessClipboard";
  permission java.awt.AWTPermission "accessEventQueue";
  permission java.awt.AWTPermission "showWindowWithoutWarningBanner";
  permission java.lang.RuntimePermission "exitVM";
  permission java.lang.RuntimePermission "loadLibrary";
  permission java.lang.RuntimePermission "queuePrintJob";
  permission java.net.SocketPermission "*", "connect";
  permission java.net.SocketPermission "localhost:1024-", "accept,listen";
  permission java.io.FilePermission "*", "read,write";
  permission java.util.PropertyPermission "*", "read";

};

// J2EE 1.4 permissions for client container - expanded ear file code base
grant codeBase "file:${com.ibm.websphere.client.applicationclient.archivedir}/-" {
  permission java.awt.AWTPermission "accessClipboard";
  permission java.awt.AWTPermission "accessEventQueue";
  permission java.awt.AWTPermission "showWindowWithoutWarningBanner";
  permission java.lang.RuntimePermission "exitVM";
  permission java.lang.RuntimePermission "loadLibrary";
  permission java.lang.RuntimePermission "queuePrintJob";
  permission java.net.SocketPermission "*", "connect";
  permission java.net.SocketPermission "localhost:1024-", "accept,listen";
  permission java.io.FilePermission "*", "read,write";
  permission java.util.PropertyPermission "*", "read";
};
```

All of the client containers and applets on the local node are granted the updated permissions when they start. If some client containers or applets on a node require permissions that are not defined as defaults in the `java.policy` file and the default `client.policy` file, update the `client.policy` file. The missing permission creates the java.security.AccessControlException exception. The missing permission is listed in the exception data, for example,

```
java.security.AccessControlException: access denied (java.io.FilePermission
C:\WebSphere\AppServer\java\jre\lib\ext\mail.jar read)
```

The previous two lines of sample code are one continuous line, but presented as such for illustrative purposes only.

When a client program receives this exception and adding this permission is justified, add a permission to the `client.policy` file, for example, grant codebase "file:*user_client_installed_location*" { permission java.io.FilePermission "`C:\WebSphere\AppServer\java\jre\lib\ext\mail.jar`", "read"; };.

To decide whether to add a permission, refer to Access control exception for Java 2 security.

If you update the policy file, you must restart the browser and any client applications.

## Developing with programmatic security APIs for web applications

Use this information to programmatically secure APIs for web applications.

### Before you begin

Programmatic security is used by security-aware applications when declarative security alone is not sufficient to express the security model of the application.

The authenticate, login, logout, getRemoteUser, isUserInRole and getAuthType servlet security methods are methods of the javax.servlet.http.HttpServletRequest interface. For more detailed information about these servlet security methods, read the Servlet security methods article.

**Note:**

> The logout, login, and authenticate APIs are new for Java Servlet 3.0 in this release of WebSphere Application Server.

You can configure several options for web authentication that determine how the web client interacts with protected and unprotected Uniform Resource Identifiers (URI). Also, you can specify whether WebSphere Application Server challenges the web client for basic authentication information if the certificate authentication for the HTTPS client fails. For more information, see the Selecting an authentication mechanism article.

When the isUserInRole method is used, declare a security-role-ref element in the deployment descriptor with a role-name subelement containing the role name that is passed to this method, or use the @DeclareRoles annotation. Because actual roles are created during the assembly stage of the application, you can use a logical role as the role name and provide enough hints to the assembler in the description of the security-role-ref element to link that role to the actual role. During assembly, the assembler creates a role-link subelement to link the role name to the actual role. Creation of a security-role-ref element is possible if an assembly tool, such as Rational Application Developer, is used. You also can create the security-role-ref element during assembly stage using an assembly tool.

### Procedure

1. Add the required security methods in the servlet code.
2. Create a security-role-ref element with the **role-name** field. If a security-role-ref element is not created during development, make sure it is created during the assembly stage.

### Results

A programmatically secured servlet application.

### Example

These steps are required to secure an application programmatically. This action is particularly useful when a web application needs to access external resources and wants to control the access to external resources using its own authorization table (external-resource to remote-user mapping). In this case, use the getUserPrincipal or the getRemoteUser methods to get the remote user, then the application can consult its own authorization table to perform authorization. The remote user information also can help

retrieve the corresponding user information from an external source such as a database or from an enterprise bean. You can use the isUserInRole method in a similar way.

After development, you can create a security-role-ref element:

```
<security-role-ref>
   <description>Provide hints to assembler for linking this role
               name to an actual role here<\description>
   <role-name>Mgr<\role-name>
</security-role-ref>
```

During assembly, the assembler creates a role-link element:

```
<security-role-ref>
   <description>Hints provided by developer to map the role
               name to the role-link</description>
   <role-name>Mgr</role-name>
   <role-link>Manager</role-link>
</security-role-ref>
```

You can add programmatic servlet security methods inside any servlet doGet, doPost, doPut, and doDelete service methods. The following example depicts using a programmatic security API:

```
public void doGet(HttpServletRequest request,
HttpServletResponse response) {

   ....
   // to logoff the current user
  request.logout();

   // to login with a new user
   request.login("bob","bobpwd")

   // to get remote user using getUserPrincipal()
   java.security.Principal principal = request.getUserPrincipal();
   String remoteUser = principal.getName();

   // to get remote user using getRemoteUser()
   remoteUser = request.getRemoteUser();

   // to check if remote user is granted Mgr role
   boolean isMgr = request.isUserInRole("Mgr");

   // use the above information in any way as needed by
   // the application
   ....

}
```

You can programmatic login with a user ID and password inside any servlet doGet, doPost, doPut, and doDelete service methods. The following example depicts using a programmatic login/logout API:

```
public void doGet(HttpServletRequest request,
HttpServletResponse response) {

   ....
   // to logout the current user. If you are not already authenticate, then no need to call the logout() method.
   request.logout();

   // to login with a new user
   request.login("utle","mypwd")

   // the user utle subject now set on the thread and the LTPA SSO cookie is set in the response
   ....

}
```

You can programmatic authenticate with a different identity inside any servlet doGet, doPost, doPut, and doDelete service methods. In this example, if the web servlet is configured to use basicAuth, the web server returns a response code 401, the login prompt is displayed, and you can enter the user ID and password to authenticate. The following example depicts using a programmatic login/logout API:

```
public void doGet(HttpServletRequest request,
HttpServletResponse response) {

   ....
   // to logout the current user. If you are not already authenticate, then no need to call the logout() method.

   // to login with a new user
   request.authenticate(response);
```

```
   // the new user subject now set on the thread and the LTPA SSO cookie is set in the response
   ....

}
```

When developing Servlet 3.0 modules, the value of the rolename argument in isCallerInRole method can be defined using Java annotations instead of declaring a security-role-ref elements in the deployment descriptor.

```
@javax.annotation.security.DeclareRoles("Mgr")
public void doGet(HttpServletRequest request,
HttpServletResponse response) {

   ....

   // to get remote user using getUserPrincipal()
   java.security.Principal principal = request.getUserPrincipal();
   String remoteUser = principal.getName();

   // to get remote user using getRemoteUser()
   remoteUser = request.getRemoteUser();

   // to check if remote user is granted Mgr role
   boolean isMgr = request.isUserInRole("Mgr");

   // use the above information in any way as needed by
   // the application
   ....

}
```

The following example depicts a web application or servlet using the programmatic security model.

This example illustrates one use and not necessarily the only use of the programmatic security model. The application can use the information that is returned by the getUserPrincipal, isUserInRole, and the getRemoteUser methods in any other way that is meaningful to that application. Use the declarative security model whenever possible.

File : HelloServlet.java

```
public class HelloServlet extends javax.servlet.http.HttpServlet {

 public void doPost(
  javax.servlet.http.HttpServletRequest request,
  javax.servlet.http.HttpServletResponse response)
  throws javax.servlet.ServletException, java.io.IOException {
 }
public void doGet(
  javax.servlet.http.HttpServletRequest request,
  javax.servlet.http.HttpServletResponse response)
  throws javax.servlet.ServletException, java.io.IOException {

        String s = "Hello";

        // get remote user using getUserPrincipal()
        java.security.Principal principal = request.getUserPrincipal();
        String remoteUserName = "";
        if( principal != null )
          remoteUserName = principal.getName();
// get remote user using getRemoteUser()
        String remoteUser = request.getRemoteUser();

        // check if remote user is granted Mgr role
        boolean isMgr = request.isUserInRole("Mgr");

        // display Hello username for managers and bob.
        if ( isMgr || remoteUserName.equals("bob") )
            s = "Hello " + remoteUserName;

   String message =  "<html> \n" +
             "<head><title>Hello Servlet</title></head>\n" +
         "<body> /n +"
    "<h1> "  +s+ </h1>/n " +
  byte[] bytes = message.getBytes();

  // displays "Hello" for ordinary users
        // and displays "Hello username" for managers and "bob".
        response.getOutputStream().write(bytes);
 }

}
```

After developing the servlet, you can create a security role reference for the HelloServlet servlet as shown in the following example:

```
<security-role-ref>
     <description> </description>
     <role-name>Mgr</role-name>
</security-role-ref>
```

## What to do next

After developing an application, use an assembly tool to create roles and to link the actual roles to role names in the security-role-ref elements. See the information about securing web applications using an assembly tool.

***Servlet security methods:***

The authenticate, login, logout, getRemoteUser, isUserInRole and getAuthType servlet security methods are methods of the javax.servlet.http.HttpServletRequest interface.

**authenticate**

**Note:** The authenticate, login and logout servlet security methods are new for Java Servlet 3.0 in this release of WebSphere Application Server.

The authenticate method authenticates a user by using the WebSphere Application Server container login mechanism configured for the servlet context.

The syntax of the authenticate method is as follows:

```
boolean authenticate(HttpServletResponse response))
```

The previous example uses the following element:

**`response`**
The HttpServletResponse associated with the HttpServletRequest.

The authenticate method returns `true` when authentication has been established or authentication is successful.

The authenticate method returns `false` if authentication is incomplete and the underlying login mechanism has committed, in the response, the message and HTTP status code to be returned to the user.

A java.io.IOException occurs if an error occurs while writing the response.

A ServletException occurs if the authentication failed, and the caller is responsible for handling the error (for example, the underlying login mechanism did not establish the message and the HTTP status code to be returned to the user).

**Note:** When the authenticate method is called, be aware of the following:

- WebSphere Application Server returns `HTTP 401` code to a client.
- The method depends on the WebSphere Application Server container login mechanism that is configured for the servlet context. For example, if you have a form login defined for this servlet, it prompts for a user name and password. The client sends the user ID and password to WebSphere Application Server for authentication.

**Important:** Make sure that the authenticate method returns `true` before using the new subject to call another service. For example:

```
Boolean authResultTrue = req.authenticate(response);
  if (!authResultTrue) {
 return;
} else {
 // Use the new invocation subject to call other services.
       }
```

### login

The login method authenticates a user to the WebSphere Application Server with a user ID and password. If authentication is successful, it creates a user subject on the thread and Lightweight Third Party Authentication (LTPA) cookies (if single sign-on (SSO) is enabled).

The syntax of the login method is as follows:

```
login(java.lang.String username, java.lang.String password)
```

The previous example uses the following elements:

**username**
The string value that corresponds to the login identifier of the user.

**password**
The password of the user.

A ServletException occurs if the configured login mechanism does not support username and password authentication, if an identity had already been authenticated (prior to the call to login), or if validation of the provided username and password fails.

**Note:** You can set the security custom property com.ibm.websphere.security.webAlwaysLogin to `true` and it will authenticate to the WebSphere application with the username and password, even if it is already authenticated.

For more information about modifying security custom properties, read the Modifying an existing custom property in a global security configuration or in a security domain configuration article.

**Note:** The login method always uses the user ID and password to authenticate to the WebSphere application server and even the SSO information that is present in the HttpServletRequest.

**Note:** The authenticate and login methods set the invocation subject to the new subject. If the caller subject is null, it then sets the caller subject to the new subject. If the caller subject is not null, then the caller subject is not set to the new subject.

Since the authenticate and login methods set the invocation subject to the new subject, the RunAs defined by the run-As attribute in deployment descriptor, security annotation or dynamic annotation is ignored.

### logout

The logout method logs the user out of the WebSphere Application Server and invalidates the HTTP session. During this process, WebSphere Application Server completes the following processes:

- Clears the LTPA cookies if SSO is enabled
- Invalidates the HTTP session
- Removes the user from the authentication cache
- Removes the user subject from the thread
- Clears the caller and invocation subjects
- Sets the authentication type to `null`

After logging out, access to a protected web resource requires re-authentication and the getUserPrincipal, getRemoteUser and getAuthType methods return `null`.

The syntax of the logout method is as follows:

```
logout()
```

A ServletException occurs if the logout fails.

### Audit event types for the authenticate, login and logout methods

To audit authenticate, login and logout methods, you must create or extend some audit event type files. These event type are not part of the default event type files.

*Table 153. Audit event types for the authenticate, login, and logout methods.*

*The audit event types required for the authenticate, login, and logout methods are:*

| Method | Audit event name | Audit outcome of the event |
|---|---|---|
| authenticate/login | SECURITY_AUTHN | SUCCESS and or FAILURE |
| logout | SECURITY_AUTHN_TERMINATE | SUCCESS |
| logout | SECURITY_AUTHN_TERMINATE | FAILURE |

### isUserInRole

(String role name): Returns `true` if the remote user is granted the specified security role. If the remote user is not granted the specified role, or if no user is authenticated, it returns `false`.

### getRemoteUser

The getRemoteUser method returns the login of the user that makes the request if the user has been authenticated. If the user has not been authenticated, the getRemoteUser method returns `null`.

### getAuthType

The getAuthType method returns the name of the authentication scheme that is used to protect the servlet. If the servlet is not protected, the getAuthType method returns `null`.

The authentication schemes used are:

**FORM** when form-based authentication is used

**BASIC**
when basic authentication is used.

**CLIENT_CERT**
when client certificate authentication is used.

**Note:**

For both the getRemoteUser and getAuthType methods, the data that is returned depends upon whether security is enabled in the application server where the servlet is deployed. The following possibilities exist:

- If application security is enabled and a servlet is protected, then the getRemoteUser method returns the login and the getAuthType method returns the configured authentication scheme.
- If application security is not enabled, both methods return `null`.

***Web authentication settings:***

Use this page to specify the web authentication settings that are associated with a web client.

To view this administrative console page, complete the following steps:

1. Click **Security > Global security**.
2. Under Authentication, expand **Web and SIP security** and click **General settings**.

You can override the global Web authentication settings that you select on this panel by specifying one or more of the following system properties on the server level. Complete the following steps to specify one of these system properties:

1. Click **Servers > Application servers >** *server_name*.
2. Under Server infrastructure, click **Java and Process Management > Process definition**.
3. Under Additional properties, click **Java Virtual Machine > Custom properties > New**

*Table 154. Web authentication system property values. This table lists the web authentication system property values.*

| Property name | Value | Explanation |
|---|---|---|
| com.ibm.wsspi.security.web.webAuthReq | `lazy` | This value is equivalent to the **Authenticate only when the URI is protected** option.<br><br>**Note:** You can set webAuthReq differently through the administrative console or scripting when using a global or a security domain, but the global level always takes precedence. |
| com.ibm.wsspi.security.web.webAuthReq | `persisting` | This value is equivalent to the **Use available authentication data when an unprotected URI is accessed** option. |
| com.ibm.wsspi.security.web.webAuthReq | `always` | This value is equivalent to the **Authenticate when any URI is accessed** option. |
| com.ibm.wsspi.security.web.failOverToBasicAuth | `true` | This value is equivalent to the **Default to basic authentication when certificate authentication for the HTTPS client fails** option. |

*Authenticate only when the URI is protected:*

The application server challenges the web client to provide authentication data when the web client accesses a Uniform Resource Identifier (URI) that is protected by a Java 2 Platform, Enterprise Edition (J2EE) role. The authenticated identity is available only when the web client accesses a protected URI.

This option is the default J2EE web authentication behavior that is also available in previous releases of WebSphere Application Server.

**Note:** When you select this option, the administrative console login page is missing images. You might encounter the following error in the administrative console: "CWLAA6003: Could not display the portlet, the portlet may not be started. Check the error logs".

The missing images and the error message are a side-effect of this option. The images do not display because the URIs for the images now need authentication, which requires you to log in. You can ignore this error message.

**Default:** Enabled

*Use available authentication data when an unprotected URI is accessed:*

The web client can access validated authenticated data that it previously could not access. This option enables the web client to call the getRemoteUser, isUserInRole, and getUserPrincipal methods to retrieve an authenticated identity from an unprotected URI.

When you select this option with the **Authenticate only when the URI is protected** option, the web client can use authenticated data when the URI is protected or not protected.

When this option is selected and Form-based authentication is being used, a WASPostParam cookie is generated during the authentication procedure of the HTTP POST request even if the target URL is unprotected. A WASPOSTParam cookie is a temporary cookie used to store HTTP POST parameters. This results in the Web client being sent the unnecessary cookie with an HTTP response. This might cause unexpected behavior when the size of the cookie is larger than the browser limit. To avoid this behavior, a custom property, com.ibm.websphere.security.util.postParamMaxCookieSize can be set to cause the security code to stop generating the cookie if the maximum size is reached.

**Important:** This option does not challenge the web client to provide authenticated data if the web client accesses an unprotected URI without authenticated data.

**Default:** Enabled

*Authenticate when any URI is accessed:*

The web client must provide authentication data regardless of whether the URI is protected.

**Default:** Disabled

*Default to basic authentication when certificate authentication for the HTTPS client fails:*

When the required HTTPS client certificate authentication fails, the application server uses the basic authentication method to challenge the web client to provide a user ID and password.

The HTTP client certification authentication that is performed by the application server security is different from the client authentication that is performed by the web server plug-in. If you configure the web server plug-in for mutual authentication and client authentication fails, the following situations will occur:

- The web server produces a error and the web request is not processed by application server security.
- The application server cannot fail over to basic authentication.

**Default:** Disabled

## Developing with programmatic APIs for EJB applications

Use this topic to programmatically secure your Enterprise JavaBeans (EJB) applications.

### About this task

Programmatic security is used by security-aware applications when declarative security alone is not sufficient to express the security model of the application. The javax.ejb.EJBContext application programming interface (API) provides two methods whereby the bean provider can access security information about the enterprise bean caller.

- **IsCallerInRole**(String rolename): Returns `true` if the bean caller is granted the security role that is specified by role name. If the caller is not granted the specified role, or if the caller is not authenticated, it returns `false`. If the specified role is granted Everyone access, it always returns `true`.
- **getCallerPrincipal**: Returns the java.security. Principal object that contains the bean caller name. If the caller is not authenticated, it returns a principal that contains an unauthorized name.

You can enable a login module to indicate which principal class is returned by these calls.

When the isCallerInRole method is used, declare a security-role-ref element in the deployment descriptor with a role-name that is subelement containing the role name that is passed to this method. Because

actual roles are created during the assembly stage of the application, you can use a logical role as the role name and provide enough hints to the assembler in the description of the security-role-ref element to link that role to an actual role. During assembly, the assembler creates a role-link subelement to link the role-name to the actual role. Creation of a security-role-ref element is possible if an assembly tool such as Rational Application Developer is used. You also can create the security-role-ref element during the assembly stage using an assembly tool.

### Procedure

1. Add the required security methods in the EJB module code.
2. Create a security-role-ref element with a role-name field for all the role names used in the isCallerInRole method. If a security-role-ref element is not created during development, make sure it is created during the assembly stage.

### Results

Performing the previous steps result in a programmatically secured EJB application.

### Example

Hard coding security policies in applications is strongly discouraged. The Java Platform, Enterprise Edition (Java EE) security model capabilities of declaratively specifying security policies is encouraged wherever possible. Use these APIs to develop security-aware EJB applications.

Using Java EE security model capabilities to specify security policies declaratively is useful when an EJB application wants to access external resources and wants to control the access to these external resources using its own authorization table (external-resource to user mapping). In this case, use the getCallerPrincipal method to get the caller identity and then the application can consult its own authorization table to perform authorization. The caller identification also can help retrieve the corresponding user information from an external source, such as database or from another enterprise bean. You can use the isCallerInRole method in a similar way.

After development, you can create a security-role-ref element:

```
<security-role-ref>
<description>Provide hints to assembler for linking this role-name to
actual role here<\description>
<role-name>Mgr<\role-name>
</security-role-ref>
```

During assembly, the assembler creates a role-link element:

```
<security-role-ref>
<description>Hints provided by developer to map role-name to role-link</description>
<role-name>Mgr</role-name>
<role-link>Manager</role-link>
</security-role-ref>
```

You can add programmatic EJB component security methods for example isCallerInRole and getCallerPrincipal, inside any business methods of an enterprise bean. The following example of programmatic security APIs includes a session bean:

```
public class aSessionBean implements SessionBean {

       .....

       // SessionContext extends EJBContext. If it is entity bean use EntityContext
       javax.ejb.SessionContext context;

       // The following method will be called by the EJB container
       // automatically
       public void setSessionContext(javax.ejb.SessionContext ctx) {
```

```
            context = ctx; // save the session bean's context
        }

        ....

        private  void aBusinessMethod()  {
        ....

        // to get  bean's caller using getCallerPrincipal()
        java.security.Principal principal = context.getCallerPrincipal();
        String  callerId= principal.getName();

        // to check if  bean's caller is granted Mgr role
        boolean isMgr = context.isCallerInRole("Mgr");

        // use the above information in any way as needed by the
        //application

        ....
        }

        ....
}
```

When developing EJB 3.x modules, the value of the rolename argument in isCallerInRole method can be defined using Java annotations instead of declaring a security-role-ref elements in the deployment descriptor.

```
  @javax.annotation.security.DeclareRoles("Mgr")
  @Stateless           // annotation is used to indicate a session bean
  public class aSessionBean implements MyBusinessInterface { //you don't have to extend sessionbean interface
        .....
        // SessionContext extends EJBContext. In EJB 3.0 use Resource annotation to inject context
    @Resource
        javax.ejb.SessionContext context;       }

       ....

       private  void aBusinessMethod()  {
       ....

       // to get  bean's caller using getCallerPrincipal()
       java.security.Principal principal = context.getCallerPrincipal();
       String  callerId= principal.getName();

       // to check if  bean's caller is granted Mgr role
       boolean isMgr = context.isCallerInRole("Mgr");

       // use the above information in any way as needed by the
       //application

       ....
       }

       ....
}
```

## What to do next

After developing an application, use an assembly tool to create roles and to link the actual roles to role names in the security-role-ref elements. See the information about securing web applications using an assembly tool.

### *Example: Enterprise bean application code:*

The following Enterprise JavaBeans (EJB) component example illustrates the use of the isCallerInRole and the getCallerPrincipal methods in an EJB module.

Using declarative security is recommended. The following example is one way of using the isCallerInRole and the getCallerPrincipal methods. The application can use this result in any way that is suitable.

### A remote interface

```
File : Hello.java

package tests;
import java.rmi.RemoteException;
/**
 * Remote interface for Enterprise Bean: Hello
 */
public interface Hello extends javax.ejb.EJBObject {
      public abstract String getMessage()throws RemoteException;
     public abstract void setMessage(String s)throws RemoteException;
}
```

### A home interface

```
File : HelloHome.java
package tests;
/**
 * Home interface for Enterprise Bean: Hello
 */
public interface HelloHome extends javax.ejb.EJBHome {
 /**
  * Creates a default instance of Session Bean: Hello
  */
 public tests.Hello create() throws javax.ejb.CreateException,
  java.rmi.RemoteException;
}
```

### A bean implementation

```
File : HelloBean.java

package tests;
/**
 * Bean implementation class for Enterprise Bean: Hello
 */
public class HelloBean implements javax.ejb.SessionBean {
 private javax.ejb.SessionContext mySessionCtx;
 /**
  * getSessionContext
  */
 public javax.ejb.SessionContext getSessionContext() {
  return mySessionCtx;
 }
 /**
  * setSessionContext
  */
 public void setSessionContext(javax.ejb.SessionContext ctx) {
  mySessionCtx = ctx;
 }
 /**
  * ejbActivate
  */
 public void ejbActivate() {
 }
 /**
  * ejbCreate
  */
 public void ejbCreate() throws javax.ejb.CreateException {
 }
 /**
  * ejbPassivate
  */
 public void ejbPassivate() {
 }
 /**
  * ejbRemove
  */
 public void ejbRemove() {
 }
```

```
 public java.lang.String message;

      //business methods

      // all users can call getMessage()
      public String getMessage() {
          return message;
      }

      // all users can call setMessage() but only few users can set new message.
      public void setMessage(String s) {

        // get  bean's caller using getCallerPrincipal()
        java.security.Principal principal = mySessionCtx.getCallerPrincipal();
        java.lang.String  callerId= principal.getName();

        // check if  bean's caller is granted Mgr role
        boolean isMgr = mySessionCtx.isCallerInRole("Mgr");

        // only set supplied message if caller is "bob" or caller is granted Mgr role
        if ( isMgr || callerId.equals("bob") )
            message = s;
        else
            message = "Hello";
      }

}
```

After the development of the entity bean, create a security role reference in the deployment descriptor under the session bean, Hello:

```
<security-role-ref>
     <description>Only Managers can call setMessage() on this bean (Hello)</description>
     <role-name>Mgr</role-name>
</security-role-ref>
```

For an explanation of how to create a <security-role-ref> element, see Securing enterprise bean applications. Use the information under Map security-role-ref and role-name to role-link to create the element.

# Customizing web application login

You can create a form login page and an error page to authenticate a user.

## Before you begin

A web client or a browser can authenticate a user to a Web server using one of the following mechanisms:

- **HTTP basic authentication**: A web server requests the Web client to authenticate and the web client passes a user ID and a password in the HTTP header.
- **HTTPS client authentication**: This mechanism requires a user (web client) to possess a public key certificate. The web client sends the certificate to a web server that requests the client certificates. This authentication mechanism is strong and uses the Hypertext Transfer Protocol with Secure Sockets Layer (HTTPS) protocol.
- **Form-based Authentication**: A developer controls the look and feel of the login screens using this authentication mechanism.

The Hypertext Transfer Protocol (HTTP) basic authentication transmits a user password from the web client to the web server in simple base64 encoding. Form-based authentication transmits a user password from the browser to the web server in plain text. Therefore, both HTTP basic authentication and form-based authentication are not very secure unless the HTTPS protocol is used.

The web application deployment descriptor contains information about which authentication mechanism to use. When form-based authentication is used, the deployment descriptor also contains entries for login

and error pages. A login page can be either an HTML page or a JavaServer Pages (JSP) file. This login page is displayed on the web client side when a secured resource (servlet, JSP file, HTML page) is accessed from the application. On authentication failure, an error page is displayed. You can write login and error pages to suit the application needs and control the look and feel of these pages. During assembly of the application, an assembler can set the authentication mechanism for the application and set the login and error pages in the deployment descriptor.

Form login uses the servlet sendRedirect method, which has several implications for the user. The sendRedirect method is used twice during form login:

- The sendRedirect method initially displays the form login page in the web browser. It later redirects the web browser back to the originally requested protected page. The sendRedirect(String URL) method tells the web browser to use the HTTP GET request to get the page that is specified in the web address. If HTTP POST is the first request to a protected servlet or JavaServer Pages (JSP) file, and no previous authentication or login occurred, then HTTP POST is not delivered to the requested page. However, HTTP GET is delivered because form login uses the sendRedirect method, which behaves as an HTTP GET request that tries to display a requested page after a login occurs.
- Using HTTP POST, you might experience a scenario where an unprotected HTML form collects data from users and then posts this data to protected servlets or JSP files for processing, but the users are not logged in for the resource. To avoid this scenario, structure your web application or permissions so that users are forced to use a form login page before the application performs any HTTP POST actions to protected servlets or JSP files.

## Procedure

1. Create a form login page with the required look and feel, including the required elements to perform form-based authentication.
2. Create an error page. You can program error pages to retry authentication or to display an appropriate error message.
3. Place the login page and error page in the web application archive (`.war`) file relative to the top directory. For example, if the login page is configured as `/login.html` in the deployment descriptor, place it in the top directory of the WAR file. An assembler can also perform this step using the assembly tool.
4. Create a form logout page and insert it to the application only when the web application requires a form-based authentication mechanism.

   By default the URL to the logout page should point to the host to which the request was made or its domain. Otherwise, a generic logout page is displayed. If you need to point this URL to a different host, then you need to set the com.ibm.websphere.security.logoutExitPageDomainList property in the `security.xml` file with a list of URLs that are allowed for the logout page. You can choose to allow any logout exit page to be used by setting the com.ibm.websphere.security.allowAnyLogoutExitPageHost property to a value of true. Setting this property to true might open your systems to a potential URL redirect attacks.

## Example: Form login

You can use the WebSphere Application Server login facilities to implement and configure form login procedures. Use the following technologies for WebSphere Application Server and Java Platform, Enterprise Edition (Java EE) login functionality:

- Java EE form-based login
- Java EE servlet filter with login
- IBM extension: form-based login

The form login sample is part of the Technology Samples package. For more information on how to access the form login sample, see Accessing the samples.

### Form login usage

For the authentication to proceed appropriately, the action of the login form must always have the j_security_check action. The following example shows how to code the form into the HTML page:

```
<form method="POST" action="j_security_check">
<input type="text" name="j_username">
<input type="text" name="j_password">
<\form>
```

Use the **j_username** input field to get the user name, and use the **j_password** input field to get the user password.

On receiving a request from a web client, the web server sends the configured form page to the client and preserves the original request. When the web server receives the completed form page from the web client, the server extracts the user name and password from the form and authenticates the user. On successful authentication, the web server redirects the call to the original request. If authentication fails, the web server redirects the call to the configured error page.

The following example depicts a login page in HTML (`login.html`):

```
<!DOCTYPE HTML PUBLIC "-//W3C/DTD HTML 4.0 Transitional//EN">
<html>
<META HTTP-EQUIV = "Pragma" CONTENT="no-cache">
<title> Security FVT Login Page </title>
<body>
<h2>Form Login</h2>
<FORM METHOD=POST ACTION="j_security_check">
<p>
<font size="2"> <strong> Enter user ID and password: </strong></font>
<BR>
<strong> User ID</strong> <input type="text" size="20" name="j_username">
<strong> Password </strong>  <input type="password" size="20" name="j_password">
<BR>
<BR>
<font size="2">  <strong> And then click this button: </strong></font>
<input type="submit" name="login" value="Login">
</p>

</form>
</body>
</html>
```

The following example depicts an error page in a JSP file:

```
<!DOCTYPE HTML PUBLIC "-//W3C/DTD HTML 4.0 Transitional//EN">
<html>
<head><title>A Form login authentication failure occurred</head></title>
<body>
<H1><B>A Form login authentication failure occurred</H1></B>
<P>Authentication may fail for one of many reasons. Some possibilities include:
<OL>
<LI>The user-id or password may be entered incorrectly; either misspelled or the
wrong case was used.
<LI>The user-id or password does not exist, has expired, or has been disabled.
</OL>
</P>
</body>
</html>
```

After an assembler configures the web application to use form-based authentication, the deployment descriptor contains the login configuration as shown:

```
<login-config id="LoginConfig_1">
<auth-method>FORM<auth-method>
<realm-name>Example Form-Based Authentication Area</realm-name>
<form-login-config id="FormLoginConfig_1">
<form-login-page>/login.html</form-login-page>
<form-error-page>/error.jsp</form-error-page>
</form-login-config>
</login-config>
```

A sample web application archive (WAR) file directory structure that shows login and error pages for the previous login configuration follows:

```
META-INF
     META-INF/MANIFEST.MF
     login.html
     error.jsp
     WEB-INF/
     WEB-INF/classes/
     WEB-INF/classes/aServlet.class
```

### Form logout

*Form logout* is a mechanism to log out without having to close all Web-browser sessions. After logging out of the form logout mechanism, access to a protected web resource requires re-authentication. This feature is not required by J2EE specifications, but it is provided as an additional feature in WebSphere Application Server security.

Suppose that you want to log out after logging into a web application and perform some actions. A form logout works in the following manner:
1. The logout-form URI is specified in the web browser and loads the form.
2. The user clicks **Submit** on the form to log out.
3. The WebSphere Application Server security code logs the user out. During this process, the Application Server completes the following processes:
   a. Clears the Lightweight Third Party Authentication (LTPA) / single sign-on (SSO) cookies
   b. Invalidates the HTTP session
   c. Removes the user from the authentication cache
4. Upon logout, the user is redirected to a logout exit page.

Form logout does not require any attributes in a deployment descriptor. The form-logout page is an HTML or a JavaServer Pages (JSP) file that is included with the web application. The form-logout page is like most HTML forms except that like the form-login page, the form-logout page has a special post action. This post action is recognized by the web container, which dispatches the post action to a special internal form-logout servlet. The post action in the form-logout page must be `ibm_security_logout`.

You can specify a logout-exit page in the logout form and the exit page can represent an HTML or a JSP file within the same web application to which the user is redirected after logging out. Additionally, the logout-exit page permits a fully qualified URL in the form of `http://`*`hostname`*`:`*`port`*`/`*`URL`*. The logout-exit page is specified as a parameter in the form-logout page. If no logout-exit page is specified, a default logout HTML message is returned to the user.

Here is a sample form logout HTML form. This form configures the logout-exit page to redirect the user back to the login page after logout.

```
<!DOCTYPE HTML PUBliC "-//W3C/DTD HTML 4.0 Transitional//EN">
<html>
  <META HTTP-EQUIV = "Pragma" CONTENT="no-cache">
  <title>Logout Page </title>
  <body>
  <h2>Sample Form Logout</h2>
      <FORM METHOD=POST ACTION="ibm_security_logout" NAME="logout">
      <p>
      <BR>
      <BR>
      <font size="2"><strong> Click this button to log out: </strong></font>
      <input type="submit" name="logout" value="Logout">
      <INPUT TYPE="HIDDEN" name="logoutExitPage" VALUE="/login.html">
      </p>
      </form>
  </body>
</html>
```

## What to do next

After developing login and error pages, add them to the Web application. Use the assembly tool to configure an authentication mechanism and insert the developed login page and error page in the deployment descriptor of the application.

## Developing servlet filters for form login processing

You can control the look and feel of the login screen using the form-based login mechanism. In form-based login, you specify a login page that is used to retrieve the user ID and password information. You also can specify an error page that displays when authentication fails.

## About this task

If additional authentication or additional processing is required before and after authentication, servlet filters are an option. Servlet filters can dynamically intercept requests and responses to transform or to use the information that is contained in the requests or responses. One or more servlet filters can be attached to a servlet or to a group of servlets. Servlet filters also can attach to JavaServer Pages (JSP) files and HTML pages. All of the attached servlet filters are called before the servlet is invoked.

Both form-based login and servlet filters are supported by any servlet Version 2.3 specification-complaint web container. The form login servlet performs the authentication and servlet filters perform additional authentication, auditing, or logging information.

To perform pre-login and post-login actions using servlet filters, configure these filters for either form login page support or for the /j_security_check URL. The j_security_check is posted by a form login page with the j_username parameter that contains the user name and the j_password parameter that contains the password. A servlet filter can use the user name parameter and password information to perform more authentication or other special needs.

## Procedure

1. A servlet filter implements the javax.servlet.Filter class. Implement three methods in the filter class:
   - **init(javax.servlet.FilterConfig cfg)**. This method is called by the container once, when the servlet filter is placed into service. The FilterConfig passed to this method contains the init-parameters of the servlet filter. Specify the init-parameters for a servlet filter during configuration using the assembly tool.
   - **destroy**. This method is called by the container when the servlet filter is taken out of a service.
   - **doFilter(ServletRequest req, ServletResponse res, FilterChain chain)**. This method is called by the container for every servlet request that maps to this filter before invoking the servlet. The FilterChain chain that is passed to this method can be used to invoke the next filter in the chain of filters. The original requested servlet runs when the last filter in the chain calls the chain.doFilter method. Therefore, all filters call the chain.doFilter method for the original servlet to run after filtering. If an additional authentication check is implemented in the filter code and results in failure, the original servlet does not run. The chain.doFilter method is not called and can be redirected to some other error page.
2. If a servlet maps to many servlet filters, servlet filters are called in the order that is listed in the `web.xml` deployment descriptor of the application. Place the servlet filter class file in the `WEB-INF/classes` directory of the application.

## Example

### An example of a servlet filter.

This login filter can map to the /j_security_check URL to perform pre-login and post-login actions.

```
import javax.servlet.*;
     public class LoginFilter implements Filter {
     protected FilterConfig filterConfig;
     // Called once when this filter is instantiated.
     // If mapped to j_security_check, called
     // very first time j_security_check is invoked.
     public void init(FilterConfig filterConfig) throws ServletException {
        this.filterConfig = filterConfig;
        }
     public void destroy() {
        this.filterConfig = null;
        }
      // Called for every request that is mapped to this filter.
     // If mapped to j_security_check,
     // called for every  j_security_check action
     public void doFilter(ServletRequest request,
     ServletResponse response, FilterChain chain)
         throws java.io.IOException, ServletException   {
         // perform pre-login action here
         chain.doFilter(request, response);
```

```
         // calls the next filter in chain.
         // j_security_check if this filter is
         // mapped to j_security_check.
        // perform post-login action here.
                }
       }
```

### Using servlet filters to perform pre-login and post-login processing during form login

This example illustrates one way that the servlet filters can perform pre-login and post-login processing during form login.

Servlet filter source code: LoginFilter.java

```
/**
 * A servlet filter example: This example filters j_security_check and
 * performs pre-login action to determine if the user trying to log in
 * is in the revoked list. If the user is on the revoked list, an error is
 * sent back to the browser.
 *
 * This filter reads the revoked list file name from the FilterConfig
 * passed in the init() method. It reads the revoked user list file and
 * creates a revokedUsers list.
 *
 * When the doFilter method is called, the user logging in is checked
 * to make sure that the user is not on the revoked Users list.
 *
 */

import javax.servlet.*;
import javax.servlet.http.*;
import java.io.*;

public class LoginFilter implements Filter {

   protected FilterConfig filterConfig;

   java.util.List revokeList;

   /**
    * init() : init() method called when the filter is instantiated.
    * This filter is instantiated the first time j_security_check is
    * invoked for the application (When a protected servlet in the
    * application is accessed).
    */
   public void init(FilterConfig filterConfig) throws ServletException {
      this.filterConfig = filterConfig;

      // read revoked user list
      revokeList = new java.util.ArrayList();
      readConfig();
   }

   /**
    * destroy() : destroy() method called when the filter is taken
    * out of service.
    */
   public void destroy() {
      this.filterConfig = null;
      revokeList = null;
   }

   /**
    * doFilter() : doFilter() method called before the servlet to
    * which this filter is mapped is invoked. Since this filter is
    * mapped to j_security_check,this method is called before
    * j_security_check action is posted.
    */
   public void doFilter(ServletRequest request, ServletResponse response,
FilterChain chain) throws java.io.IOException, ServletException {

      HttpServletRequest req = (HttpServletRequest)request;
      HttpServletResponse res = (HttpServletResponse)response;

      // pre login action

      // get username
      String username = req.getParameter("j_username");

      // if user is in revoked list send error
      if ( revokeList.contains(username) ) {
      res.sendError(javax.servlet.http.HttpServletResponse.SC_UNAUTHORIZED);
      return;
      }
```

```
      // call next filter in the chain : let j_security_check authenticate
      // user
      chain.doFilter(request, response);

      // post login action

   }

   /**
    * readConfig() : Reads revoked user list file and creates a revoked
    * user list.
    */
   private void readConfig() {
      if ( filterConfig != null ) {

         // get the revoked user list file and open it.
         BufferedReader in;
         try {
               String filename = filterConfig.getInitParameter("RevokedUsers");
               in = new BufferedReader( new FileReader(filename));
         } catch ( FileNotFoundException fnfe) {
               return;
         }

         // read all the revoked users and add to revokeList.
         String userName;
         try {
               while ( (userName = in.readLine()) != null )
                   revokeList.add(userName);
         } catch (IOException ioe) {
         }

      }

   }

}
```

**Important:** In the previous code sample, the line that begins `public void doFilter(ServletRequest request` is broken into two lines for illustrative purposes only. The `public void doFilter(ServletRequest request` line and the line after it are one continuous line.

An example of the `web.xml` file that shows the LoginFilter filter configured and mapped to the j_security_check URL:

```
<filter id="Filter_1">
    <filter-name>LoginFilter</filter-name>
    <filter-class>LoginFilter</filter-class>
         <description>Performs pre-login and post-login operation</description>
    <init-param>
    <param-name>RevokedUsers</param-name>
    <param-value>c:\WebSphere\AppServer\installedApps\
                          <app-name>\revokedUsers.lst</param-value>
    </init-param>
</filter-id>

<filter-mapping>
 <filter-name>LoginFilter</filter-name>
     <url-pattern>/j_security_check</url-pattern>
</filter-mapping>
```

An example of a revoked user list file:

```
user1
cn=user1,o=ibm,c=us
user99
cn=user99,o=ibm,c=us
```

### *Configuring servlet filters for form login processing:*

IBM Rational Application Developer or an assembly tool can configure the servlet filters. Two steps are involved in configuring a servlet filter.

#### Procedure

1. Name the servlet filter and assign the corresponding implementation class to the servlet filter.

Optionally, assign initialization parameters that get passed to the init method of the servlet filter.After configuring the servlet filter, the `web.xml` application deployment descriptor contains a servlet filter configuration similar to the following example:

```
<filter id="Filter_1">
   <filter-name>LoginFilter</filter-name>
   <filter-class>LoginFilter</filter-class>
   <description>Performs pre-login and post-login
        operation</description>
   <init-param>// optional
     <param-name>ParameterName</param-name>
     <param-value>ParameterName</param-value>
   </init-param>
</filter>
```

2. Map the servlet filter to a URL or a servlet.

   After mapping the servlet filter to a URL or a servlet, the `web.xml` application deployment descriptor contains servlet mapping similar to the following example:

```
<filter-mapping>
   <filter-name>LoginFilter</filter-name>
   <url-pattern>/j_security_check</url-pattern>
              // can be servlet <servlet>servletName</servlet>
</filter-mapping>
```

**Example**

You can use servlet filters to replace the CustomLoginServlet servlet, and to perform additional authentication, auditing, and logging.

The WebSphere Application Server Samples provide a form login sample that demonstrates how to use the WebSphere Application Server login facilities to implement and configure form login procedures. The sample integrates the following technologies to demonstrate the WebSphere Application Server and Java Platform, Enterprise Edition (Java EE) login functionality:

- Java EE form-based login
- Java EE servlet filter with login
- IBM extension: form-based login

The form login sample is part of the Technology Samples package.

# Secure transports with JSSE and JCE programming interfaces

This topic provides detailed information about transport security using Java Secure Socket Extension (JSSE) and Java Cryptography Extension (JCE) programming interfaces. Within this topic, there is a description of the IBM version of the Java Cryptography Extension Federal Information Processing Standard (IBMJCEFIPS).

## Java Secure Socket Extension

Java Secure Socket Extension (JSSE) provides the transport security for WebSphere Application Server. JSSE provides the application programming interface (API) framework and the implementation of the APIs for Secure Sockets Layer (SSL) and Transport Layer Security (TLS) protocols, including functionality for data encryption, message integrity, and authentication.

JSSE APIs are integrated into the Java 2 SDK, Standard Edition (J2SDK), Version 5. The API package for JSSE APIs is `javax.net.ssl.*`. Documentation for using JSSE APIs can be found in the J2SE 6 API documentation that is located at `http://java.sun.com/javase/6/docs/technotes/guides/security/jsse/JSSERefGuide.html`.

Several JSSE providers ship with the Java 2 SDK Version 5 that comes with WebSphere Application Server. The IBMJSSE provider is used in previous WebSphere Application Server releases. Associated with the IBMJSSE provider is the IBMJSSEFIPS provider, which is used when FIPS is enabled on the

server. Both of these providers do not work with the Java Message Service (JMS) and HTTP transports in WebSphere Application Server Version 8.0. These transports take advantage of the J2SDK Verison 5 network input/output (NIO) asynchronous channels.

For more information on the new IBMJSSE2 provider, please review the documentation located at `http://www.ibm.com/developerworks/java/jdk/security/60/`.

## Customizing Java Secure Socket Extension

You can customize a number of aspects of JSSE by plugging in different implementations of Cryptography Package Provider, X509Certificate and HTTPS protocols, or specifying different default keystore files, key manager factories, and trust manager factories. The following table summarizes which aspects can be customized, what the defaults are, and which mechanisms are used to provide customization.

*Table 155. Customizable items. You can customize the following key aspects:*

| Customizable item | Default | How to customize |
|---|---|---|
| X509Certificate | X509Certificate implementation from IBM | The cert.provider.x509v1 security property |
| HTTPS protocol | Implementation from IBM | The java.protocol.handler.pkgs system property |
| Cryptography Package Provider | IBMJSSE2 | A security.provider.n= line in security properties file. See description. |
| Default keystore | None | The * javax.net.ssl.keyStore system property |
| Default truststore | jssecacerts, if it exists. Otherwise, cacerts | The * javax.net.ssl.trustStore system property |
| Default key manager factory | IbmX509 | The ssl.KeyManagerFactory.algorithm security property |
| Default trust manager factory | IbmX509 | The ssl.TrustManagerFactory.algorithm security property |

For aspects that you can customize by setting a system property, statically set the system property by using the -D option of the Java command. You can set the system property using the administrative console, or set the system property dynamically by calling the java.lang.System.setProperty method in your code: System.setProperty(propertyName,"propertyValue").

For aspects that you can customize by setting a Java security property, statically specify a security property value in the java.security properties file. The security property is propertyName=propertyValue. Dynamically set the Java security property by calling the java.security.Security.setProperty method in your code.

The java.security properties file is located in the following directory:

*app_server_root*`/java/jre/lib/security` directory.

## Application Programming Interface

The JSSE provides a standard application programming interface (API) that is available in packages of the `javax.net` file, `javax.net.ssl` file, and the `javax.security.cert` file. The APIs cover:

- Sockets and SSL sockets
- Factories to create the sockets and SSL sockets
- Secure socket context that acts as a factory for secure socket factories
- Key and trust manager interfaces
- Secure HTTP URL connection classes
- Public key certificate API

You can find more information documented for the JSSE APIs if you access the following information:

**Version 1.6**

1. Access the http://www.ibm.com/developerworks/java/jdk/security/ website.

2. Click Java 1.6.
3. Click Javadoc HTML documentation in the Java Secure Socket Extension (JSSE) Guide section.

## Samples using Java Secure Socket Extension

The Java Secure Socket Extension (JSSE) also provides samples to demonstrate its functionality. The Java Secure Socket Extension (JSSE) also provides samples to demonstrate its functionality. You can access the samples in the following location:

**Version 1.6**

1. Access the http://www.ibm.com/developerworks/java/jdk/security/ website.
2. Click Java 1.6.
3. Click `jssedocs_samples.zip` in the Java Secure Socket Extension (JSSE) Guide section.

*Table 156. Extracted files. This table lists the following extracted files:*

| Files | Description |
|---|---|
| ClientJsse.java | Demonstrates a simple client and server interaction using JSSE. All enabled cipher suites are used. |
| OldServerJsse.java | Back-level samples |
| ServerPKCS12Jsse.java | Demonstrates a simple client and server interaction using JSSE with the PKCS12 keystore file. All enabled cipher suites are used. |
| ClientPKCS12Jsse.java | Demonstrates a simple client and server interaction using JSSE with the PKCS12 keystore file. All enabled cipher suites are used. |
| UseHttps.java | Demonstrates accessing an SSL or non-SSL web server using the Java protocol handler of the com.ibm.net.ssl.www.protocol class. The URL is specified with the `http` or `https` prefix. The HTML that is returned from this site is displayed. |

See more instructions in the source code. Follow these instructions before you run the samples.

## Permissions for Java 2 security

You might need the following permissions to run an application with JSSE: This list is for reference only.
- java.util.PropertyPermission "java.protocol.handler.pkgs", "write"
- java.lang.RuntimePermission "writeFileDescriptor"
- java.lang.RuntimePermission "readFileDescriptor"
- java.lang.RuntimePermission "accessClassInPackage.sun.security.x509"
- java.io.FilePermission "${user.install.root}${/}etc${/}.keystore", "read"
- java.io.FilePermission "${user.install.root}${/}etc${/}.truststore", "read"

For the IBMJSSE provider:
- java.security.SecurityPermission "putProviderProperty.IBMJSSE"
- java.security.SecurityPermission "insertProvider.IBMJSSE"

For the SUNJSSE provider:
- java.security.SecurityPermission "putProviderProperty.SunJSSE"
- java.security.SecurityPermission "insertProvider.SunJSSE"

## Debugging

By configuring through the javax.net.debug system property, JSSE provides the following dynamic debug tracing: -Djavax.net.debug=true.

A value of true turns on the trace facility, provided that the debug version of JSSE is installed.

## Documentation

See the Security: Resources for learning topic for documentation references to JSSE.

## JCE

Java Cryptography Extension (JCE) provides cryptographic, key and hash algorithms for WebSphere Application Server. JCE provides a framework and implementations for encryption, key generation, key agreement, and Message Authentication Code (MAC) algorithms. Support for encryption includes symmetric, asymmetric, block and stream ciphers.

## IBMJCE

The IBM version of the Java Cryptography Extension (IBMJCE) is an implementation of the JCE cryptographic service provider that is used in WebSphere Application Server. The IBMJCE is similar to SunJCE, except that the IBMJCE offers more algorithms:

- Cipher algorithm (AES, DES, TripleDES, PBEs, Blowfish, and so on)
- Signature algorithm (SHA1withRSA, MD5withRSA, SHA1withDSA)
- Message digest algorithm (MD5, MD2, SHA1, SHA-256, SHA-384, SHA-512)
- Message authentication code (HmacSHA1, HmacMD5)
- Key agreement algorithm (DiffieHellman)
- Random number generation algorithm (IBMSecureRandom, SHA1PRNG)
- Key store (JKS, JCEKS, PKCS12, JCERACFKS [z/OS only])

The IBMJCE belongs to the com.ibm.crypto.provider.* packages.

For further information, see the information on JCE on the following website: http://www.ibm.com/developerworks/java/jdk/security/60/.

## IBMJCEFIPS

The IBM version of the Java Cryptography Extension Federal Information Processing Standard (IBMJCEFIPS) is an implementation of the JCE cryptographic service provider that is used in WebSphere Application Server. The IBMJCEFIPS service provider implements the following:

- Signature algorithms (SHA1withDSA, SHA1withRSA)
- Cipher algorithms (AES, TripleDES, RSA)
- Key agreement algorithm (DiffieHellman)
- Key (pair) generator (DSA, AES, TripleDES, HmacSHA1, RSA, DiffieHellman)
- Message authentication code (MAC) (HmacSHA1)
- Message digest (MD5, SHA-1, SHA-256, SHA-384, SHA-512)
- Algorithm parameter generator (DiffieHellman, DSA)
- Algorithm parameter (AES, DiffieHellman, DES, TripleDES, DSA)
- Key factory (DiffieHellman, DSA, RSA)
- Secret key factory (AES, TripleDES)
- Certificate (X.509)
- Secure random (IBMSecureRandom)

## Application Programming Interface

Java Cryptography Extension (JCE) has a provider-based architecture. Providers can be plugged into the JCE framework by implementing the APIs that are defined by the JCE. The JCE APIs cover:

- Symmetric bulk encryption, such as DES, RC2, and IDEA
- Symmetric stream encryption, such as RC4
- Asymmetric encryption, such as RSA
- Password-based encryption (PBE)
- Key agreement
- Message authentication codes

There is more information documented for the JCE APIs on the `http://www.ibm.com/developerworks/java/jdk/security/` website.

### Samples using Java Cryptography Extension

There are samples located on the `http://www.ibm.com/developerworks/java/jdk/security/` website in the `jceDocs_samples.zip` file. Unzip the file and locate the following samples in the `jceDocs/samples` directory:

*Table 157. Samples using Java Cryptography Extension. This table describes samples using Java Cryptography Extension.*

| File | Description |
|---|---|
| SampleDSASignature.java | Demonstrates how to generate a pair of DSA keys (a public key and a private key) and use the key to digitally sign a message using the SHA1withDSA algorithm |
| SampleMarsCrypto.java | Demonstrates how to generate a Mars secret key, and how to do Mars encryption and decryption |
| SampleMessageDigests.java | Demonstrates how to use the message digest for MD2 and MD5 algorithms |
| SampleRSACrypto.java | Demonstrates how to generate an RSA key pair, and how to do RSA encryption and decryption |
| SampleRSASignatures.java | Demonstrates how to generate a pair of RSA keys (a public key and a private key) and use the key to digitally sign a message using the SHA1withRSA algorithm |
| SampleX509Verification.java | Demonstrates how to verify X509 certificates |

### Documentation

Refer to the Security: Resources for learning topic for documentation on JCE.

## Configuring Federal Information Processing Standard Java Secure Socket Extension files

Use this topic to configure Federal Information Processing Standard Java Secure Socket Extension files.

### About this task

In WebSphere Application Server, the Java Secure Socket Extension (JSSE) provider used is the IBMJSSE2 provider. This provider delegates encryption and signature functions to the Java Cryptography Extension (JCE) provider. Consequently, IBMJSSE2 does not need to be Federal Information Processing Standard (FIPS)-approved because it does not perform cryptography. However, the JCE provider requires FIPS-approval.

WebSphere Application Server provides a FIPS-approved IBMJCEFIPS provider that IBMJSSE2 can utilize. The IBMJCEFIPS provider that is shipped in WebSphere Application Server Version 8.0 supports the following SSL ciphers:

- SSL_RSA_WITH_AES_128_CBC_SHA
- SSL_RSA_WITH_3DES_EDE_CBC_SHA
- SSL_RSA_FIPS_WITH_3DES_EDE_CBC_SHA
- SSL_DHE_RSA_WITH_AES_128_CBC_SHA
- SSL_DHE_RSA_WITH_3DES_EDE_CBC_SHA
- SSL_DHE_DSS_WITH_AES_128_CBC_SHA
- SSL_DHE_DSS_WITH_3DES_EDE_CBC_SHA

Even though the IBMJSSEFIPS provider is still present, the runtime does not use this provider. If IBMJSSEFIPS is specified as a contextProvider, WebSphere Application Server automatically defaults to the IBMJSSE2 provider (with the IBMJCEFIPS provider) for supporting FIPS. When enabling the **Use the United States Federal Information Processing Standard (FIPS) algorithms** option on the server SSL certificate and key management panel, the runtime always uses IBMJSSE2, despite the contextProvider

that you specify for SSL (IBMJSSE, IBMJSSE2 or IBMJSSEFIPS). Also, because FIPS requires the SSL protocol be TLS, the runtime always uses TLS when FIPS is enabled, regardless of the SSL protocol setting in the SSL repertoire. This simplifies the FIPS configuration in Version 8.0 because an administrator needs to enable only the **Use the United States Federal Information Processing Standard (FIPS) algorithms** option on the server SSL certificate and key management panel to enable all transports using SSL.

## Procedure

1. Click **Security > SSL certificate and key management**.
2. Select the **Use the United States Federal Information Processing Standard (FIPS) algorithms** option and click **Apply**. This option makes IBMJSSE2 and IBMJCEFIPS the active providers.
3. Accommodate Java clients that must access enterprise beans.

   Change the `com.ibm.security.useFIPS` property value from `false` to `true` in the *profile_root*`/properties/ssl.client.props` file.
4. Ensure that the com.ibm.ssl.protocol property within the *profile_root*`/properties/ssl.client.props` file is set to SSL_TLS.
5. Ensure that the `java.security` file includes the provider.

   Edit the `java.security` file to insert the IBMJCEFIPS provider (com.ibm.crypto.fips.provider.IBMJCEFIPS) before the IBMJCE provider, and also renumber the other providers in the provider list. The IBMJCEFIPS provider must be in the `java.security` file provider list.

   The `java.security` file is located in the *WAS_HOME*`/java/jre/lib/security/properties` directory.

   Edit the `java.security` file to comment out the line with the IBMJCEFIPS provider and also renumber the rest of the provider list. The IBMJCEFIPS provider must be in the `java.security` file provider list.

   Edit the `java.security` file to comment out the line with the IBMJCE provider, uncomment the line with the IBMJCEFIPS provider, and save the file.

   The IBM SDK `java.security` file looks like the following example after completing this step:

```
security.provider.1=com.ibm.crypto.fips.provider.IBMJCEFIPS
security.provider.2=com.ibm.crypto.provider.IBMJCE
security.provider.3=com.ibm.jsse.IBMJSSEProvider
security.provider.4=com.ibm.jsse2.IBMJSSEProvider2
security.provider.5=com.ibm.security.jgss.IBMJGSSProvider
 security.provider.6=com.ibm.security.cert.IBMCertPath
security.provider.7=com.ibm.crypto.pkcs11impl.provider.IBMPKCS11Impl
security.provider.8=com.ibm.security.cmskeystore.CMSProvider
security.provider.9=com.ibm.security.jgss.mech.spnego.IBMSPNEGO
security.provider.10=com.ibm.security.sasl.IBMSASL
security.provider.11=com.ibm.xml.crypto.IBMXMLCryptoProvider
security.provider.12=com.ibm.xml.enc.IBMXMLEncProvider
security.provider.13=org.apache.harmony.security.provider.PolicyProvider
```

   If you are using the Sun Java SE Development Kit, the `java.security` file looks like the following example after completing this step:

```
security.provider.1=sun.security.provider.Sun
security.provider.2=com.ibm.crypto.fips.provider.IBMJCEFIPS
security.provider.3=com.ibm.crypto.provider.IBMJCE
security.provider.4=com.ibm.jsse.IBMJSSEProvider
security.provider.5=com.ibm.jsse2.IBMJSSEProvider2
security.provider.6=com.ibm.security.jgss.IBMJGSSProvider
security.provider.7=com.ibm.security.cert.IBMCertPath
#security.provider.12=com.ibm.crypto.pkcs11.provider.IBMPKCS11
security.provider.8=com.ibm.security.jgss.mech.spnego.IBMSPNEGO
security.provider.9=com.ibm.security.cmskeystore.CMSProvider
security.provider.10=com.ibm.security.sasl.IBMSASL
security.provider.11=com.ibm.xml.crypto.IBMXMLCryptoProvider
security.provider.12=com.ibm.xml.enc.IBMXMLEncProvider
```

## What to do next

After completing these steps, a FIPS-approved JSSE or JCE provider offers increased encryption capabilities. However, when you use FIPS-approved providers:

- By default, Microsoft Internet Explorer might not have TLS enabled. To enable TLS, open the Internet Explorer browser and click **Tools > Internet Options**. On the Advanced tab, select the Use TLS 1.0 option.

  **Note:** Netscape Version 4.7.*x* and earlier versions might not support TLS.
- If you have an administrative client that uses a SOAP connector and you enable FIPS, add the following line to the *profile_root*/properties/soap.client.props file:

  ```
  com.ibm.ssl.contextProvider=IBMJSSEFIPS
  ```
- When you select the **Use the Federal Information Processing Standard (FIPS)** option on the SSL certificate and key management panel, the Lightweight Third-Party Authentication (LTPA) token format is not backwards-compatible with previous releases of WebSphere Application Server. However, you can import the LTPA keys from a previous version of the application server.

**Attention:** The following error might occur when you attempt to stop WebSphere Application Server after enabling the FIPS option:

```
ADMU3007E: Exception com.ibm.websphere.management.exception.ConnectorException
```

Uncomment the following entry in the java.security file if it was previously removed or commented out, then restart the server:

```
security.provider.2=com.ibm.crypto.provider.IBMJCE
```

**Note:** When enabling FIPS, you cannot configure cryptographic token devices in the SSL repertoires. IBMJSSE2 must use IBMJCEFIPS when utilizing cryptographic services for FIPS.

The following FIPS 140-2 approved cryptographic providers that are the only devices that are supported with the FIPS option:

- IBMJCEFIPS (certificate 376)
- IBM Cryptography for C (ICC) (certificate 384)

The relevant certificates are listed on the NIST website: Cryptographic Module Validation Program FIPS 140-1 and FIPS 140-2 Pre-validation List

To unconfigure the FIPS provider, reverse the changes that you made in the previous steps. After you reverse the changes, verify that you have made the following changes to the sas.client.props, soap.client.props, and java.security files:

- In the ssl.client.props file, you must change the com.ibm.security.useFIPS value to false.
- In the java.security file, you must change the FIPS provider to a non-FIPS provider.

  If you are using the IBM SDK java.security file, you must change the first provider to a non-FIPS provider as shown in the following example:

```
#security.provider.1=com.ibm.crypto.fips.provider.IBMJCEFIPS
security.provider.1=com.ibm.crypto.provider.IBMJCE
security.provider.2=com.ibm.jsse.IBMJSSEProvider
security.provider.3=com.ibm.jsse2.IBMJSSEProvider2
security.provider.4=com.ibm.security.jgss.IBMJGSSProvider
security.provider.5=com.ibm.security.cert.IBMCertPath
#security.provider.6=com.ibm.crypto.pkcs11.provider.IBMPKCS11
```

  If you are using the Sun JDK java.security file, you must change the third provider to a non-FIPS provider as shown in the following example:

```
security.provider.1=sun.security.provider.Sun
security.provider.2=com.ibm.security.jgss.IBMJGSSProvider
security.provider.3=com.ibm.crypto.fips.provider.IBMJCEFIPS
security.provider.4=com.ibm.crypto.provider.IBMJCE
security.provider.5=com.ibm.jsse.IBMJSSEProvider
security.provider.6=com.ibm.jsse2.IBMJSSEProvider2
security.provider.7=com.ibm.security.cert.IBMCertPath
#security.provider.8=com.ibm.crypto.pkcs11.provider.IBMPKCS11
```

# Implementing tokens for security attribute propagation

As part of an extensible architecture, WebSphere Application Server enables you to implement your own tokens in which to propagate security attributes.

## About this task

The following topics are covered in this section:

## Procedure

- Implementing a custom propagation token
- Implementing a custom authorization token
- Implementing a custom a single sign-on token
- Implementing a custom authentication token
- Propagating a custom Java serializable object

## Implementing a custom propagation token for security attribute propagation

This topic explains how you might create your own propagation token implementation, which is set on the running thread and propagated downstream.

### About this task

The default propagation token usually is sufficient for propagating attributes that are not user-specific. Consider writing your own implementation if you want to accomplish one of the following tasks:

- Isolate your attributes within your own implementation.
- Serialize the information using custom serialization. You must deserialize the bytes at the target and add that information back on the thread by plugging in a custom login module into the inbound system login configurations. This task also might include encryption and decryption.

To implement a custom propagation token, you must complete the following steps:

### Procedure

1. Write a custom implementation of the PropagationToken interface. Many different methods are available for implementing the PropagationToken interface. However, make sure that the methods that are required by the PropagationToken interface and the token interface are fully implemented.

   After you implement this interface, you can place it in the *app_server_root*/classes directory. Alternatively, you can place the class in any private directory. However, make sure that the WebSphere Application Server class loader can locate the class and that it is granted the appropriate permissions. You can add the Java archive (JAR) file or directory that contains this class into the server.policy file so that it has the required permissions for the server code.

   **Tip:** All of the token types that are defined by the propagation framework have similar interfaces. The token types are marker interfaces that implement the com.ibm.wsspi.security.token.Token interface. This interface defines most of the methods. If you plan to implement more than one token type, consider creating an abstract class that implements the com.ibm.wsspi.security.token.Token interface. All of your token implementations, including the propagation token, might extend the abstract class and then most of the work is complete.

   To see an implementation of the propagation token, see “Example: com.ibm.wsspi.security.token.PropagationToken implementation” on page 1229.
2. Add and receive the custom propagation token during WebSphere Application Server logins. This task is typically accomplished by adding a custom login module to the various application and system login configurations. You also can add the implementation from an application. However, to deserialize the information, you need to plug in a custom login module, which is discussed in “Propagating a custom Java serializable object for security attribute propagation” on page 1256. The

WSSecurityPropagationHelper class has APIs that are used to set a propagation token on the thread and to retrieve the token from the thread to make updates.

The code sample in “Example: Custom propagation token login module” on page 1233 shows how to determine if the login is an initial login or a propagation login. The difference between these login types is whether the WSTokenHolderCallback callback contains propagation data. If the callback does not contain propagation data, initialize a new custom propagation token implementation and set it on the thread. If the callback contains propagation data, look for your specific custom propagation token TokenHolder instance, convert the byte array back into your custom PropagationToken object, and set it back on the thread. The code sample shows both instances.

You can add attributes any time your custom propagation token is added to the thread. If you add attributes between requests and the getUniqueId method changes, the Common Secure Interoperability Version 2 (CSIv2) client session is invalidated so that it can send the new information downstream. Adding attributes between requests can affect performance. In many cases, you want the downstream requests to receive the new propagation token information.

To add the custom propagation token to the thread, call the WSSecurityPropagationHelper.addPropagationToken method. This call requires the WebSphereRuntimePerMission "setPropagationToken" Java 2 Security permission.

3. Add your custom login module to WebSphere Application Server system login configurations that already contain the com.ibm.ws.security.server.lm.wsMapDefaultInboundLoginModule login module for receiving serialized versions of your custom propagation token You can also add this login module to any of the application logins where you might want to generate your custom propagation token on the thread during the login. Alternatively, you can generate the custom PropagationToken implementation from within your application. However, to deserialize it, you need to add the implementation to the system login modules.

## Results

After completing these steps, you have implemented a custom PropagationToken.

***Example: com.ibm.wsspi.security.token.PropagationToken implementation:***

Use this file to see an example of a propagation token implementation. The following sample code does not extend an abstract class, but implements the com.ibm.wsspi.security.token.PropagationToken interface directly. You can implement the interface directly, but it might cause you to write duplicate code. However, you might choose to implement the interface directly if considerable differences exist between how you handle the various token implementations.

For information on how to implement a custom propagation token, see “Implementing a custom propagation token for security attribute propagation” on page 1228.

```
package com.ibm.websphere.security.token;

### *Example: Custom propagation token login module:*

This example shows how to determine if the login is an initial login or a propagation login.

```
public customLoginModule()
{
 public void initialize(Subject subject, CallbackHandler callbackHandler,
         Map sharedState, Map options)
 {
  // (For more information on what to do during initialization, see
     // Developing custom login modules for a system login configuration for JAAS.)
 }

 public boolean login() throws LoginException
 {
  // (For more information on what to do during login, see
     // Developing custom login modules for a system login configuration for JAAS.)

  // Handles the WSTokenHolderCallback to see if this is an initial
     // or propagation login.
  Callback callbacks[] = new Callback[1];
  callbacks[0] = new WSTokenHolderCallback("Authz Token List: ");

  try
  {
   callbackHandler.handle(callbacks);
  }
  catch (Exception e)
  {
   // handle exception
  }

  // Receives the ArrayList of TokenHolder objects (the serialized tokens)
  List authzTokenList = ((WSTokenHolderCallback) callbacks[0]).getTokenHolderList();

  if (authzTokenList != null)
  {
   // Iterates through the list looking for your custom token
   for (int i=0; i<authzTokenList.size(); i++)
   {
    TokenHolder tokenHolder = (TokenHolder)authzTokenList.get(i);

    // Looks for the name and version of your custom PropagationToken implementation
    if (tokenHolder.getName().equals("
             com.ibm.websphere.security.token.CustomPropagationTokenImpl") &&
        tokenHolder.getVersion() == 1)
    {
     // Passes the bytes into your custom PropagationToken constructor
            //  to deserialize
     customPropToken = new
      com.ibm.websphere.security.token.CustomPropagationTokenImpl(tokenHolder.
                 getBytes());

    }
   }
  }
  else // This is not a propagation login. Create a new instance of
         // your PropagationToken implementation
  {
   // Adds a new custom propagation token. This is an initial login
   customPropToken = new com.ibm.websphere.security.token.CustomPropagationTokenImpl();
```

```
   // Adds any initial attributes
   if (customPropToken != null)
   {
    customPropToken.addAttribute("key1", "value1");
    customPropToken.addAttribute("key1", "value2");
    customPropToken.addAttribute("key2", "value1");
    customPropToken.addAttribute("key3", "something different");
   }
  }

  // Note: You can add the token to the thread during commit in case
     // something happens during the login.
 }

```

## Implementing a custom authorization token for security attribute propagation

This task explains how you might create your own AuthorizationToken implementation, which is set in the login Subject and propagated downstream.

## About this task

The default AuthorizationToken usually is sufficient for propagating attributes that are user-specific. Consider writing your own implementation if you want to accomplish one of the following tasks:

- Isolate your attributes within your own implementation.
- Serialize the information using custom serialization. You must deserialize the bytes at the target and add that information back on the thread. This task also might include encryption and decryption.
- Affect the overall uniqueness of the Subject using the getUniqueID() application programming interface (API).

To implement a custom authorization token, you must complete the following steps:

## Procedure

1. Write a custom implementation of the AuthorizationToken interface. There are many different methods for implementing the AuthorizationToken interface. However, make sure that the methods required by the AuthorizationToken interface and the token interface are fully implemented.

   After you implement this interface, you can place it in the *app_server_root*/classes directory. Alternatively, you can place the class in any private directory. However, make sure that the WebSphere Application Server class loader can locate the class and that it is granted the appropriate permissions. You can add the Java archive (JAR) file or directory that contains this class into the server.policy file so that it has the necessary permissions that are needed by the server code.

   **Tip:** All of the token types defined by the propagation framework have similar interfaces. Basically, the token types are marker interfaces that implement the com.ibm.wsspi.security.token.Token interface. This interface defines most of the methods. If you plan to implement more than one token type, consider creating an abstract class that implements the com.ibm.wsspi.security.token.Token interface. All of your token implementations, including the AuthorizationToken, might extend the abstract class and then most of the work is completed.

   To see an implementation of AuthorizationToken, see “Example: com.ibm.wsspi.security.token.AuthorizationToken implementation” on page 1236
2. Add and receive the custom AuthorizationToken during WebSphere Application Server logins. This task is typically accomplished by adding a custom login module to the various application and system login configurations. However, in order to deserialize the information, you must plug in a custom login module, which is discussed in “Propagating a custom Java serializable object for security attribute propagation” on page 1256. After the object is instantiated in the login module, you can add the object to the Subject during the commit() method.

   If you only want to add information to the Subject to get propagated, see “Propagating a custom Java serializable object for security attribute propagation” on page 1256. If you want to ensure that the information is propagated, want to do you own custom serialization, or want to specify the uniqueness for Subject caching purposes, then consider writing your own AuthorizationToken implementation.

   The code sample in “Example: custom AuthorizationToken login module” on page 1239 shows how to determine if the login is an initial login or a propagation login. The difference between these login types is whether the WSTokenHolderCallback contains propagation data. If the callback does not contain propagation data, initialize a new custom AuthorizationToken implementation and set it into the Subject. If the callback contains propagation data, look for your specific custom AuthorizationToken TokenHolder instance, convert the byte[] back into your custom AuthorizationToken object, and set it back into the Subject. The code sample shows both instances.

   You can make your AuthorizationToken read-only in the commit phase of the login module. If you do not make the token read-only, then attributes can be added within your applications.
3. Add your custom login module to WebSphere Application Server system login configurations that already contain the com.ibm.ws.security.server.lm.wsMapDefaultInboundLoginModule for receiving serialized versions of your custom authorization token.

Because this login module relies on information in the sharedState added by the com.ibm.ws.security.server.lm.wsMapDefaultInboundLoginModule, add this login module after com.ibm.ws.security.server.lm.wsMapDefaultInboundLoginModule. For information on how to add your custom login module to the existing login configurations, see Developing custom login modules for a system login configuration for JAAS.

## Results

After completing these steps, you have implemented a custom AuthorizationToken.

### *Example: com.ibm.wsspi.security.token.AuthorizationToken implementation:*

Use this file to see an example of a AuthorizationToken implementation. The following sample code does not extend an abstract class, but rather implements the com.ibm.wsspi.security.token.AuthorizationToken interface directly. You can implement the interface directly, but it might cause you to write duplicate code. However, you might choose to implement the interface directly if there are considerable differences between how you handle the various token implementations.

For information on how to implement a custom AuthorizationToken, see “Implementing a custom authorization token for security attribute propagation” on page 1234.

 java.util.Map _sharedState = null;
}
```

## Implementing a custom single sign-on token for security attribute propagation

You can create your own single sign-on token implementation. The single sign-on token implementation is set in the login Subject and added to the HTTP response as an HTTP cookie.

### About this task

The cookie name is the concatenation of the SingleSignonToken.getName application programming interface (API) and the SingleSignonToken.getVersion API. There is no delimiter. When you add a single sign-on token to the Subject, it also gets propagated horizontally and downstream in case the Subject is used for other web requests. You must deserialize your custom single sign-on token when you receive it from a propagation login. Consider writing your own implementation if you want to accomplish one of the following tasks:

- Isolate your attributes within your own implementation.
- Serialize the information using custom serialization. Encrypt the information because it is out to the HTTP response and is available on the Internet. You must deserialize or decrypt the bytes at the target and add that information back into the Subject.
- Affect the overall uniqueness of the Subject using the getUniqueID API.

To implement a custom single sign-on token, complete the following steps:

### Procedure

1. Write a custom implementation of the SingleSignonToken interface.

   Many different methods are available for implementing the SingleSignonToken interface. However, make sure the methods that are required by the SingleSignonToken interface and the token interface are fully implemented.

   After you implement this interface, you can place it in the *app_server_root*/classes directory. Alternatively, you can place the class in any private directory. However, make sure that the WebSphere Application Server class loader can locate the class and that it is granted the appropriate permissions.

You can add the Java archive (JAR) file or directory that contains this class into the `server.policy` file so that it has the required permissions for the server code.

**Tip:** All of the token types that are defined by the propagation framework have similar interfaces. Basically, the token types are marker interfaces that implement the com.ibm.wsspi.security.token.Token interface. This interface defines most of the methods. If you plan to implement more than one token type, consider creating an abstract class that implements the com.ibm.wsspi.security.token.Token interface. All of your token implementations, including the single sign-on token, might extend the abstract class and then most of the work is complete.

To see an implementation of the single sign-on token, see “Example: A com.ibm.wsspi.security.token.SingleSignonToken implementation”

2. Add and receive the custom single sign-on token during WebSphere Application Server logins. This task is typically accomplished by adding a custom login module to the various application and system login configurations. However, to deserialize the information, you need to plug in a custom login module, which is discussed in a subsequent step. After the object is instantiated in the login module, you can add it to the Subject during the commit method.

   The code sample in “Example: A custom single sign-on token login module” on page 1246, shows how to determine if the login is an initial login or a propagation login. The difference is whether the WSTokenHolderCallback callback contains propagation data. If the callback does not contain propagation data, initialize a new custom single sign-on token implementation and set it into the Subject. Also, look for the HTTP cookie from the HTTP request if the HTTP request object is available in the callback. You can get your custom single sign-on token both from a horizontal propagation login and from the HTTP request. However, it is recommended that you make the token available in both places because then the information arrives at any front-end application server, even if that server does not support propagation.

   You can make your single sign-on token read-only in the commit phase of the login module. If you make the token read-only, additional attributes cannot be added within your applications.

   **Restriction:**

   - HTTP cookies have a size limitation. Size restrictions should be included in the documentation for your specific browser.
   - The WebSphere Application Server runtime does not handle cookies that it does not generate, so this cookie is not used by the runtime.
   - The SingleSignonToken object, when in the Subject, does affect the cache lookup of the Subject if you return something in the getUniqueID method.

3. Get the HTTP cookie from the HTTP request object during login or from an application. The sample code that is found in “Example: An HTTP cookie retrieval” on page 1248 shows how you can retrieve the HTTP cookie from the HTTP request, decode the cookie so that it is back to your original bytes, and create your custom SingleSignonToken object from the bytes.
4. Add your custom login module to WebSphere Application Server system login configurations that already contain the com.ibm.ws.security.server.lm.wsMapDefaultInboundLoginModule for receiving serialized versions of your custom propagation token. Because this login module relies on information in the sharedState state that is added by the com.ibm.ws.security.server.lm.wsMapDefaultInboundLoginModule login module, add this login module after the com.ibm.ws.security.server.lm.wsMapDefaultInboundLoginModule login module.

   For information on adding your custom login module into the existing login configurations, see Developing custom login modules for a system login configuration for JAAS.

## Results

After completing these steps, you have implemented a custom single sign-on token.

***Example: A com.ibm.wsspi.security.token.SingleSignonToken implementation:***

Use this file to see an example of a single sign-on implementation. The following sample code does not extend an abstract class, but implements the com.ibm.wsspi.security.token.SingleSignonToken interface directly. You can implement the interface directly, but it might cause you to write duplicate code. However, you might choose to implement the interface directly if considerable differences exist between how you handle the various token implementations.

For information on how to implement a custom single sign-on token, see “Implementing a custom single sign-on token for security attribute propagation” on page 1241.

### *Example: A custom single sign-on token login module:*

This file shows how to determine if the login is an initial login or a propagation login.

For information on initialization and on what to do during login and commit, see Developing custom login modules for a system login configuration for JAAS.

```
public customLoginModule()
{
 public void initialize(Subject subject, CallbackHandler callbackHandler,
     Map sharedState, Map options)
 {
  _sharedState = sharedState;
 }

 public boolean login() throws LoginException
 {
     // Handles the WSTokenHolderCallback to see if this is an initial or
     // propagation login.
  Callback callbacks[] = new Callback[1];
  callbacks[0] = new WSTokenHolderCallback("Authz Token List: ");

  try
  {
   callbackHandler.handle(callbacks);
  }
  catch (Exception e)
  {
```

```
 // handle exception
}

// Receives the ArrayList of TokenHolder objects (the serialized tokens)
List authzTokenList = ((WSTokenHolderCallback) callbacks[0]).getTokenHolderList();

if (authzTokenList != null)
{
 // iterate through the list looking for your custom token
 for (int i=0; i
 for (int i=0; i<authzTokenList.size(); i++)
 {
  TokenHolder tokenHolder = (TokenHolder)authzTokenList.get(i);

  // Looks for the name and version of your custom SingleSignonToken
       // implementation
  if (tokenHolder.getName().equals("myCookieName")
           && tokenHolder.getVersion() == 1)
  {
   // Passes the bytes into your custom SingleSignonToken constructor
         // to deserialize
   customSSOToken = new
    com.ibm.websphere.security.token.CustomSingleSignonTokenImpl
                (tokenHolder.getBytes());

  }
 }
}
else
        // This is not a propagation login. Create a new instance of your
        // SingleSignonToken implementation
{
     // Gets the principal from the default SingleSignonToken. This principal
     //  must match all tokens.
 defaultAuthToken = (com.ibm.wsspi.security.token.AuthenticationToken)
  sharedState.get(com.ibm.wsspi.security.auth.callback.Constants.WSAUTHTOKEN_KEY);
 String principal = defaultAuthToken.getPrincipal();

 // Adds a new custom single sign-on (SSO) token. This is an initial login.
     //  Pass the principal into the constructor
 customSSOToken = new com.ibm.websphere.security.token.
         CustomSingleSignonTokenImpl(principal);

 // add any initial attributes
 if (customSSOToken != null)
 {
  customSSOToken.addAttribute("key1", "value1");
  customSSOToken.addAttribute("key1", "value2");
  customSSOToken.addAttribute("key2", "value1");
  customSSOToken.addAttribute("key3", "something different");
 }
}

   // Note: You can add the token to the Subject during commit in case something
   // happens during the login.
}

public boolean commit() throws LoginException
{
 if (customSSOToken != null)
 {
  // Sets the customSSOToken token into the Subject
  try
  {
   public final SingleSignonToken customSSOTokenPriv = customSSOToken;
         // Do this in a doPrivileged code block so that application code does not
         // need to add additional permissions
   java.security.AccessController.doPrivileged(new java.security.PrivilegedAction()
   {
    public Object run()

 com.ibm.wsspi.security.token.AuthenticationToken defaultAuthToken = null;
 java.util.Map _sharedState = null;
}
```

### *Example: An HTTP cookie retrieval:*

The following example shows you how to retrieve a cookie from an HTTP request, decode the cookie so that it is back to your original bytes, and create your custom SingleSignonToken object from the bytes. This example shows how to complete these steps from a login module. However, you also can complete these steps using a servlet.

For information on what to do during initialization, login and commit, see Developing custom login modules for a system login configuration for JAAS.

```
public customLoginModule()
{
 public void initialize(Subject subject, CallbackHandler callbackHandler,
     Map sharedState, Map options)
 {
  _sharedState = sharedState;
 }

 public boolean login() throws LoginException
 {
     // Handles the WSTokenHolderCallback to see if this is an
     // initial or propagation login.
  Callback callbacks[] = new Callback[2];
  callbacks[0] = new WSTokenHolderCallback("Authz Token List: ");
  callbacks[1] = new WSServletRequestCallback("HttpServletRequest: ");

  try
  {
   callbackHandler.handle(callbacks);
  }
  catch (Exception e)
  {
   // Handles the exception
  }

  // receive the ArrayList of TokenHolder objects (the serialized tokens)
  List authzTokenList = ((WSTokenHolderCallback) callbacks[0]).getTokenHolderList();
  javax.servlet.http.HttpServletRequest request =
         ((WSServletRequestCallback) callbacks[1]).getHttpServletRequest();

  if (request != null)
  {

   // Checks if the cookie is present
   javax.servlet.http.Cookie[] cookies = request.getCookies();
   String[] cookieStrings = getCookieValues (cookies, "myCookeName1");

   if (cookieStrings != null)
   {
    String cookieVal = null;
    for (int n=0;n<cookieStrings.length;n++)
    {
     cookieVal = cookieStrings[n];
     if (cookieVal.length()>0)
     {
               // Removes the cookie encoding from the cookie to get
               // your custom bytes
      byte[] cookieBytes =
       com.ibm.websphere.security.WSSecurityHelper.
                     convertCookieStringToBytes(cookieVal);
      customSSOToken =
       new com.ibm.websphere.security.token.
                     CustomSingleSignonTokenImpl(cookieBytes);

               // Now that you have your cookie from the request,
               // you can do something with it here, or add it
               // to the Subject in the commit() method for use later.
      if (debug || tc.isDebugEnabled())
      {

```

## Implementing a custom authentication token for security attribute propagation

This topic explains how you might create your own authentication token implementation, which is set in the login Subject and propagated downstream.

## About this task

With this implementation you can specify an authentication token that can be used by a custom login module or application. Consider writing your own implementation if you want to accomplish one of the following tasks:

- Isolate your attributes within your own implementation.
- Serialize the information using custom serialization. You must deserialize the bytes at the target and add that information back on the thread. This task also might include encryption and decryption.
- Affect the overall uniqueness of the Subject using the getUniqueID application programming interface (API).

**Important:** Custom authentication token implementations are not used by the security runtime in WebSphere Application Server to enforce authentication. WebSphere Application Security runtime uses this token in the following situations only:

- Call the getBytes method for serialization
- Call the getForwardable method to determine whether to serialize the authentication token.
- Call the getUniqueId method for uniqueness
- Call the getName and the getVersion methods for adding serialized bytes to the token holder that is sent downstream

All of the other uses are custom implementations.

To implement a custom authentication token, you must complete the following steps:

## Procedure

1. Write a custom implementation of the AuthenticationToken interface. Many different methods are available for implementing the AuthenticationToken interface. However, make sure the methods that are required by the AuthenticationToken interface and the token interface are fully implemented. After you implement this interface, you can place it in the *install_dir*/classes directory. Alternatively, you can place the class in any private directory. However, make sure that the WebSphere Application Server class loader can locate the class and that it is granted the appropriate permissions. You can add the Java archive (JAR) file or directory that contains this class into the server.policy file so the class has the necessary permissions required by the server code.

   **Tip:** All of the token types that are defined by the propagation framework have similar interfaces. The token types are marker interfaces that implement the com.ibm.wsspi.security.token.Token interface. This interface defines most of the methods. If you plan to implement more than one token type, consider creating an abstract class that implements the com.ibm.wsspi.security.token.Token interface. All of your token implementations, including the authentication token, might extend the abstract class and then most of the work is complete.

   To see an implementation of the AuthenticationToken interface, see “Example: A com.ibm.wsspi.security.token.AuthenticationToken implementation” on page 1251.
2. Add and receive the custom authentication token during WebSphere Application Server logins. This task is typically accomplished by adding a custom login module to the various application and system login configurations. However, to deserialize the information you must plug in a custom login module. After the object is instantiated in the login module, you can add the object to the Subject during the commit method.

   If you only want to add information to the Subject to get propagated, see “Propagating a custom Java serializable object for security attribute propagation” on page 1256. If you want to ensure that the information is propagated, do your own custom serialization, or specify the uniqueness for Subject caching purposes, consider writing your own authentication token implementation.

   The code sample in “Example: A custom authentication token login module” on page 1255, shows how to determine if the login is an initial login or a propagation login. The difference between these login

types is whether the WSTokenHolderCallback callback contains propagation data. If the callback does not contain propagation data, initialize a new custom authentication token implementation and set it into the Subject. If the callback contains propagation data, look for your specific custom authentication token TokenHolder instance, convert the byte array back into your custom AuthenticationToken object, and set it back into the Subject. The code sample shows both instances.

You can make your authentication token read-only in the commit phase of the login module. If you do not make the token read-only, attributes can be added within your applications.

3. Add your custom login module to WebSphere Application Server system login configurations that already contain the com.ibm.ws.security.server.lm.wsMapDefaultInboundLoginModule login module for receiving serialized versions of your custom authorization token.

   Because this login module relies on information in the shared state that is added by the com.ibm.ws.security.server.lm.wsMapDefaultInboundLoginModule login module, add this login module after the com.ibm.ws.security.server.lm.wsMapDefaultInboundLoginModule login module. For information on how to add your custom login module to the existing login configurations, see Developing custom login modules for a system login configuration for JAAS.

## Results

After completing these steps, you have implemented a custom authentication token.

### *Example: A com.ibm.wsspi.security.token.AuthenticationToken implementation:*

The following example illustrates an authentication token implementation. The following sample code does not extend an abstract class, but rather implements the com.ibm.wsspi.security.token.AuthenticationToken interface directly. You can implement the interface directly, but it might cause you to write duplicate code. However, you might choose to implement the interface directly if considerable differences exist between how you handle the various token implementations.

```
package com.ibm.websphere.security.token;

import com.ibm.websphere.security.WSSecurityException;
import com.ibm.websphere.security.auth.WSLoginFailedException;
import com.ibm.wsspi.security.token.*;
import com.ibm.websphere.security.WebSphereRuntimePermission;
import java.io.ByteArrayOutputStream;
import java.io.ByteArrayInputStream;
import java.io.DataOutputStream;
import java.io.DataInputStream;
import java.io.ObjectOutputStream;
import java.io.ObjectInputStream;
import java.io.OutputStream;
import java.io.InputStream;
import java.util.ArrayList;

### *Example: A custom authentication token login module:*

This examples shows how to determine if the login is an initial login or a propagation login.

For information on what to do during initialization, login and commit, see Developing custom login modules for a system login configuration for JAAS.

```
public customLoginModule()
{
 public void initialize(Subject subject, CallbackHandler callbackHandler,
    Map sharedState, Map options)
 {
  _sharedState = sharedState;
 }

 public boolean login() throws LoginException
 {
  // Handles the WSTokenHolderCallback to see if this is an initial or
     // propagation login.
  Callback callbacks[] = new Callback[1];
  callbacks[0] = new WSTokenHolderCallback("Authz Token List: ");

  try
  {
   callbackHandler.handle(callbacks);
  }
  catch (Exception e)
  {
   // Handles exception
  }

  // Receives the ArrayList of TokenHolder objects (the serialized tokens)
  List authzTokenList = ((WSTokenHolderCallback) callbacks[0]).getTokenHolderList();

  if (authzTokenList != null)
  {
   // Iterates through the list looking for your custom token
   for (int i=0; i<authzTokenList.size(); i++)
   {
    TokenHolder tokenHolder = (TokenHolder)authzTokenList.get(i);

          // Looks for the name and version of your custom AuthenticationToken
          // implementation
    if (tokenHolder.getName().equals("your_oid_name") && tokenHolder.getVersion() == 1)
    {
           // Passes the bytes into your custom AuthenticationToken constructor
           // to deserialize
     customAuthzToken = new
      com.ibm.websphere.security.token.
               CustomAuthenticationTokenImpl(tokenHolder.getBytes());

    }
   }
  }
  else
         // This is not a propagation login. Create a new instance of your
         // AuthenticationToken implementation
  {
       //  Gets the principal from the default AuthenticationToken. This principal
       //  should match all default tokens.
       //  Note: WebSphere Application Server runtime only enforces this for
       //  default tokens. Thus, you can choose
       //  to do this for custom tokens, but it is not required.
   defaultAuthToken = (com.ibm.wsspi.security.token.AuthenticationToken)
    sharedState.get(com.ibm.wsspi.security.auth.callback.Constants.WSAUTHTOKEN_KEY);
   String principal = defaultAuthToken.getPrincipal();
```

```
      // Adds a new custom authentication token. This is an initial login. Pass
      // the principal into the constructor
   customAuthToken = new com.ibm.websphere.security.token.
         CustomAuthenticationTokenImpl(principal);

   // Adds any initial attributes
   if (customAuthToken != null)
   {
    customAuthToken.addAttribute("key1", "value1");
    customAuthToken.addAttribute("key1", "value2");
    customAuthToken.addAttribute("key2", "value1");
    customAuthToken.addAttribute("key3", "something different");
   }
  }

     // Note: You can add the token to the Subject during commit in case
     // something happens during the login.
}

public boolean commit() throws LoginException

com.ibm.wsspi.security.token.AuthenticationToken defaultAuthToken = null;
java.util.Map _sharedState = null;
}
```

## Propagating a custom Java serializable object for security attribute propagation

This document describes how to add an object into the Subject from a login module and describes other infrastructure considerations to make sure that the Java object gets propagated.

### Before you begin

Prior to completing this task, verify that security propagation is enabled in the administrative console.

### About this task

With security attribute propagation enabled, you can propagate data either horizontally with single sign-on (SSO) enabled or downstream using Common Secure Interoperability Version 2 (CSIv2). When a login occurs, either through an application login configuration or a system login configuration, a custom login module can be plugged in to add Java serialized objects into the Subject during login. This document describes how to add an object into the Subject from a login module and describes other infrastructure

considerations to make sure that the Java object gets propagated.

## Procedure

1. Add your custom Java object into the Subject from a custom login module. A two-phase process exists for each Java Authentication and Authorization Service (JAAS) login module. WebSphere Application Server completes the following processes for each login module present in the configuration:

   **login method**
   In this step, the login configuration callbacks are analyzed, if necessary, and the new objects or credentials are created.

   **commit method**
   In this step, the objects or credentials that are created during login are added into the Subject.

   After a custom Java object is added into the Subject, WebSphere Application Server serializes the object on the sending server, deserializes the object on the receiving server, and adds the object back into the Subject downstream. However, some requirements exist for this process to occur successfully. For more information on the JAAS programming model, see the JAAS information provided in the Security: Resources for learning article.

   **Important:** Whenever you plug a custom login module into the login infrastructure of WebSphere Application Server, make sure that the code is trusted. When you put the classes together in a Java archive (JAR) file and add the file to the *app_server_root*/lib/ext/ directory, the login module has Java 2 Security AllPermissions permissions . It is recommended that you add your login module and other infrastructure classes into any private directory. However, you must modify the *profile_root*/properties/server.policy file to make sure that your private directory, Java archive (JAR) file, or both have the permissions required to run the application programming interfaces (API) that are called from the login module. Because the login module might be run after the application code on the call stack, you might add doPrivileged code so that you do not need to add additional properties to your applications.

   The following code sample shows how to add doPrivileged code. For information on what to do during initialization, login and commit, see Developing custom login modules for a system login configuration for JAAS.

```
public customLoginModule()
{
 public void initialize(Subject subject, CallbackHandler callbackHandler,
     Map sharedState, Map options)
 {

 }

 public boolean login() throws LoginException
 {
     // Construct callback for the WSTokenHolderCallback so that you
     // can determine if
     // your custom object has propagated
    Callback callbacks[] = new Callback[1];
    callbacks[0] = new WSTokenHolderCallback("Authz Token List: ");

    try
    {
         _callbackHandler.handle(callbacks);
    }
    catch (Exception e)
    {
    throw new LoginException (e.getLocalizedMessage());
    }

    // Checks to see if any information is propagated into this login
    List authzTokenList = ((WSTokenHolderCallback) callbacks[1]).
            getTokenHolderList();

    if (authzTokenList != null)
    {
        for (int i = 0; i< authzTokenList.size(); i++)
             {
            TokenHolder tokenHolder = (TokenHolder)authzTokenList.get(i);

                 //  Look for your custom object. Make sure you use
                 //  "startsWith"because there is some data appended
```

```
                //  to the end of the name indicating in which Subject
                //  Set it belongs. Example from getName():
                //  "com.acme.CustomObject (1)". The class name is
                //  generated at the sending side by calling the
                //  object.getClass().getName() method. If this object
                //  is deserialized by WebSphere Application Server,
                //  then return it and you do not need to add it here.
                //  Otherwise, you can add it below.
                //  Note: If your class appears in this list and does
                //  not use custom serialization (for example, an
                //  implementation of the Token interface described in
                //  the Propagation Token Framework), then WebSphere
                //  Application  Server automatically deserializes the
                //  Java object for you. You might just return here if
                //  it is found in the list.

           if (tokenHolder.getName().startsWith("com.acme.CustomObject"))
          return true;
       }
    }
       //  If you get to this point, then your custom object has not propagated
        myCustomObject = new com.acme.CustomObject();
        myCustomObject.put("mykey", "mydata");
}

public boolean commit() throws LoginException
{
 try
 {
      // Assigns a reference to a final variable so it can be used in
      // the doPrivileged block
  final com.acme.CustomObject myCustomObjectFinal = myCustomObject;
  // Prevents your applications from needing a JAAS getPrivateCredential
      // permission.
  java.security.AccessController.doPrivileged(new java.security.
          PrivilegedExceptionAction()
  {
   public Object run() throws java.lang.Exception
   {
           // Try not to add a null object to the Subject or an object
           // that already exists.
    if (myCustomObjectFinal != null && !subject.getPrivateCredentials().
               contains(myCustomObjectFinal))
    {
              // This call requires a special Java 2 Security permission,
              // see the JAAS application programming interface (API)
              // documentation.
     subject.getPrivateCredentials().add(myCustomObjectFinal);
    }
    return null;
   }
  });
 }
 catch (java.security.PrivilegedActionException e)
 {
  // Wraps the exception in a WSLoginFailedException
  java.lang.Throwable myException = e.getException();
  throw new WSLoginFailedException (myException.getMessage(), myException);
 }
}

// Defines your login module variables
com.acme.CustomObject myCustomObject = null;
}
```

2. Verify that your custom Java class implements the java.io.Serializable interface. An object that is added to the Subject must be serialized if you want the object to propagate. For example, the object must implement the java.io.Serializable interface. If the object is not serialized, the request does not fail, but the object does not propagate. To make sure an object that is added to the Subject is propagated, implement one of the token interfaces that is defined in topics about security attribute propagation or add attributes to one of the following existing default token implementations:

   **AuthorizationToken**
   Add attributes if they are user-specific.

   **PropagationToken**
   Add attributes that are specific to an invocation.

   If you are careful adding custom objects and follow all the steps to make sure that WebSphere Application Server can serialize and deserialize the object at each hop, then it is sufficient to use custom Java objects only.

3. Verify that your custom Java class exists on all of the systems that might receive the request.

When you add a custom object into the Subject and expect WebSphere Application Server to propagate the object, put the class definitions together in a Java archive (JAR) file and add the file to the *app_server_root*/lib/ext/ directory on all of the nodes where serialization or deserialization might occur. Also, verify that the Java class versions are the same.

4. Verify that your custom login module is configured in all of the login configurations used in your environment where you need to add your custom object during a login. Any login configuration that interacts with WebSphere Application Server generates a Subject that might be propagated outbound for an Enterprise JavaBeans (EJB) request. If you want WebSphere Application Server to propagate a custom object in all cases, make sure that the custom login module is added to every login configuration that is used in your environment. For more information, see Developing custom login modules for a system login configuration for JAAS.
5. Verify that security attribute propagation is enabled on all of the downstream servers that receive the propagated information. When an EJB request is sent to a downstream server and security attribute propagation is disabled on that server, only the authentication token is sent for backwards compatibility. Therefore, you must review the configuration to verify that propagation is enabled in all of the cells that might receive requests. You must check several places in the administrative console to make sure propagation is fully enabled.
6. Add any custom objects to the propagation exclude list that you do not want to propagate. You can configure a property to exclude the propagation of objects that match specific class names, package names, or both. For example, you can have a custom object that is related to a specific process. If the object is propagated, it does not contain valid information. You must tell WebSphere Application Server not to propagate this object. Complete the following steps to specify the object in the propagation exclude list, using the administrative console:
   a. Click **Security > Global security > Custom properties > New**.
   b. Add `com.ibm.ws.security.propagationExcludeList` in the **Name** field.
   c. Add the name of the custom object in the **Value** field. You can add a list of custom objects to the propagation exclude list, separated by a colon (:). For example, you might enter `com.acme.CustomLocalObject:com.acme.private.*`. You can enter a class name such as `com.acme.CustomLocalObject` or a package name such as `com.acme.private.*`. In this example, WebSphere Application Server does not propagate any class that equals `com.acme.CustomLocalObject` or begins with `com.acme.private.`

      Although you can add custom objects to the propagation exclude list, you must be aware of a side effect. WebSphere Application Server stores the opaque token, or the serialized Subject contents, in a local cache for the life of the single sign-on (SSO) token. The life of the SSO token, which has a default of two hours, is configured in the SSO properties on the administrative console. The information that is added to the opaque token includes only the objects not in the exclude list.

      Ensure that your SSO token timeout value is greater that the authentication cache timeout value. To modify the authentication cache, see the documentation about the authentication cache settings.

### Results

As a result of this task, custom Java serializable objects are propagated horizontally or downstream. For more information on the differences between horizontal and downstream propagation, see topics about security attribute propagation or add attributes to one of the following existing default token implementations:.

## Enabling a plugpoint for custom password encryption

Two properties govern the protection of passwords. By configuring these two properties, you can enable a plugpoint for custom password encryption.

## Before you begin

To view an example code sample that illustrates the com.ibm.wsspi.security.crypto.CustomPasswordEncryption interface, see “Plug point for custom password encryption” on page 1261.

## About this task

The encryption method is called for password processing whenever the custom class is configured and custom encryption is enabled. The decryption method is called whenever the custom class is configured and the password contains the {custom:alias} tag. The custom:alias tag is stripped prior to decryption.

## Procedure

1. To enable custom password encryption, you must configure two properties:
   - **com.ibm.wsspi.security.crypto.customPasswordEncryptionClass** - Defines the custom class that implements the com.ibm.wsspi.security.crypto.CustomPasswordEncryption password encryption interface.
   - **com.ibm.wsspi.security.crypto.customPasswordEncryptionEnabled** - Defines when the custom class is used for default password processing. When the passwordEncryptionEnabled option is not specified or set to false, and the passwordEncryptionClass class is specified, the decryption method is called whenever a {custom:alias} tag still exists in the configuration repository.
2. To configure custom password encryption, configure both of these properties in the server.xml file. How you perform this configuration is dependent on your existing directory structure. Choose one of the following ways to perform this configuration:
   - Place The custom encryption class (com.acme.myPasswordEncryptionClass) in a Java archive (JAR) file that resides in the ${WAS_INSTALL_ROOT}/classes directory. In this case, you have created the ${WAS_INSTALL_ROOT}/classes directory for this purpose.

     **Note:** WebSphere Application Server does not create the ${WAS_INSTALL_ROOT}/classes directory.
   - Place the custom encryption class (com.acme.myPasswordEncryptionClass) in a Java archive (JAR) file that resides in the ${WAS_HOME}/lib/ext directory or another valid existing directory.

   Every configuration document that contains a password (security.xml and any application bindings that contain RunAs passwords), must be saved before all of the passwords become encrypted with the custom encryption class.
3. If the custom implementation class defaults to the com.ibm.wsspi.security.crypto.CustomPasswordEncryptionImpl interface, and this class is present in the class path, then encryption is enabled by default. This simplifies the enablement process for all nodes. It is not necessary to define any other properties except for those that the custom implementation requires. To disable encryption, but still use this class for decryption, specify the following class.
   - com.ibm.wsspi.security.crypto.customPasswordEncryptionEnabled=false

## What to do next

Whenever a custom encryption class encryption operation is called, and it creates a run-time exception or a defined PasswordEncryptException exception, the WebSphere Application Server runtime uses the {xor} algorithm to encode the password. This encoding prevents the storage of the password in plain text. After the problem with the custom class has been resolved, it automatically encrypts the password the next time the configuration document is saved.

When a RunAs role is assigned a user ID and password, it currently is encoded using the WebSphere Application Server encoding function. Therefore, after the custom plug point is configured to encrypt the

passwords, it encrypts the passwords for the RunAs bindings as well. If the deployed application is moved to a cell that does not have the same encryption keys, or the custom encryption is not yet enabled, a login failure results because the password is not readable.

One of the responsibilities of the custom password encryption implementation is to manage the encryption keys. This class must decrypt any password that it encrypted. Any failure to decrypt a password renders that password to be unusable, and the password must be changed in the configuration. All encryption keys must be available for decryption there and no passwords are left using those keys. The master secret must be maintained by the custom password encryption class to protect the encryption keys.

You can manage the master secret by using a stash file for the keystore, or by using a password locator that enables the custom encryption class to locate the password so that it can be locked down.

## Plug point for custom password encryption

A plug point for custom password encryption can be created to encrypt and decrypt all passwords in WebSphere Application Server that are currently encoded or decoded using Base64-encoding.

The implementation class of this plug point has the responsibility for managing keys, determining the encryption algorithm to use, and for protecting the master secret. The WebSphere Application Server runtime stores the encrypted passwords in their existing locations, preceded with {custom:alias} tags instead of {xor} tags. The custom part of the tag indicates that it is a custom algorithm. The alias part of the tag is specified by the custom implementation, which helps to indicate how the password is encrypted. The implementation can include the key alias, encryption algorithm, encryption mode, or encryption padding.

A custom provider of this plug point must implement an interface that is designed to encrypt and decrypt passwords. The interface is called by the WebSphere Application Server runtime whenever the custom plug point is enabled. The custom algorithm becomes one of the supported algorithms when the plug point is enabled. Other supported algorithms include {xor} (standard base64 encoding) and {os400} which is used on the iSeries platform.

The following example illustrates the com.ibm.wsspi.security.crypto.CustomPasswordEncryption interface:

```
package com.ibm.wsspi.security.crypto;
public interface CustomPasswordEncryption
{

    /**
     * The encrypt operation takes a UTF-8 encoded String in the form of a byte[].
     * The byte[] is generated from String.getBytes("UTF-8").
     * An encrypted byte[] is returned from the implementation in the EncryptedInfo
     * object.  Additionally, a logical key alias is returned in the EncryptedInfo
     * objectwhich is passed back into the decrypt method to determine which key was
     * used to encrypt this password. The WebSphere Application Server runtime has
     * no knowledge of the algorithm or the key used to encrypt the data.
     *
     * @param byte[]
     * @return com.ibm.wsspi.security.crypto.EncryptedInfo
     * @throws com.ibm.wsspi.security.crypto.PasswordEncryptException
     **/
    public EncryptedInfo encrypt (byte[] decrypted_bytes) throws PasswordEncryptException;

    /**
     * The decrypt operation takes the EncryptedInfo object containing a byte[]
     * and the logical key alias and converts it to the decrypted byte[].  The
     * WebSphere Application Server runtime converts the byte[] to a String
     * using new String (byte[], "UTF-8");
     *
     * @param com.ibm.wsspi.security.crypto.EncryptedInfo
     * @return byte[]
     * @throws com.ibm.wsspi.security.crypto.PasswordDecryptException
     **/
    public byte[] decrypt (EncryptedInfo info) throws PasswordDecryptException;

    /**
     * The following is reserved for future use and is currently not
     * called by the WebSphere Application Server runtime.
     *
```

```
     * @param java.util.HashMap
     **/
    public void initialize (java.util.HashMap initialization_data);
}
```

The com.ibm.wsspi.security.crypto.EncryptedInfo class contains the encrypted bytes with the user-defined alias that is associated with the encrypted bytes. This information is passed back into the encryption method to help determine how the password was originally encrypted.

```
package com.ibm.wsspi.security.crypto;
public class EncryptedInfo
{
    private byte[] bytes;
    private String alias;

/**
 * This constructor takes the encrypted bytes and a keyAlias as parameters.
 * This constructor is used to pass to or from the WebSphere Application Server
 * runtime to enable the runtime to associate the bytes with a specific key that
 * is used to encrypt the bytes.
 */

    public EncryptedInfo (byte[] encryptedBytes, String keyAlias)
    {
        bytes = encryptedBytes;
        alias = keyAlias;
    }

/**
 * This command returns the encrypted bytes.
 *
 * @return byte[]
 */
    public byte[] getEncryptedBytes()
    {
        return bytes;
    }

/**
 * This command returns the key alias.  The key alias is a logical string that is
 * associated with the encrypted password in the model. The format is
 * {custom:keyAlias}encrypted_password. Typically, just the key alias is placed
 * here, but algorithm information can also be returned.
 *
 * @return String
 */
    public String getKeyAlias()
    {
        return alias;
    }

}
```

The encryption method is called for password processing whenever the custom class is configured and custom encryption is enabled. The decryption method is called whenever the custom class is configured and the password contains the {`custom:alias`} tag . The `custom:alias` tag is stripped prior to decryption. For more information, see Enabling custom password encryption.

# Implementing a custom authentication provider using JASPI

You can implement a custom authentication provider using Java Authentication SPI for Containers (JASPI, or sometimes called JASPIC) to handle the Java Platform, Enterprise Edition (Java EE) authentication of HTTP request and response messages destined for web applications.

## Before you begin

For JASPI authentication processing to take place, application security must be enabled in the global or domain security configuration and the server must be restarted for the configuration changes to take effect. Read the Application security topic for more information.

## About this task

**Note:** This release of WebSphere Application Server supports the JSR 196: Java Authentication SPI for Containers (JASPI, or sometimes called JASPIC) specification, which enables third-party security providers to handle the Java Platform, Enterprise Edition (Java EE) authentication of HTTP request

and response messages destined for web applications. The JASPI specification extends the pluggable authentication concepts of the Java Authentication and Authorization Service (JAAS) to the authentication of HTTP request and response messages. When application security is enabled, and a protected web resource is accessed, the web container and the security runtime collaborate to make an authentication decision for the caller. When using a third-party JASPI provider, the authentication decision is delegated to that provider.

The JASPI specification defines standard system programming interfaces that enable developers to write a pluggable custom authentication provider that can handle Java EE web authentication mechanisms as well as any extended authentication processing. The WebSphere Application Server runtime uses these standard system programming interfaces to invoke the JASPI authentication provider. Read the Servlet Container Profile section in the JSR 196: Java Authentication Service Provider Interface for Containers specification for the requirements that third-party authentication providers must satisfy for more information.

If application security is enabled with JASPI authentication, when the web resource (such as a servlet or a JavaServer Pages (JSP) file) is accessed, the security runtime checks if the web resource is mapped to a JASPI provider defined in the security configuration. If so, the runtime invokes the JASPI authentication provider to perform authentication for the HTTP request and response messages.

To implement a custom authentication provider using JASPI you must do the following:

## Procedure

1. Develop a custom JASPI authentication provider.

   WebSphere Application Server provides support for the development of custom JASPI authentication providers to be used to perform authentication for the HTTP request and response messages destined for web applications. Read “Developing a custom JASPI authentication provider” for more information.
2. Configure a new JASPI authentication provider.

   WebSphere Application Server allows an administrator to enable JASPI authentication and to define a third-party JASPI authentication provider as part of the global or domain security configuration. Read “Configuring a new JASPI authentication provider using the administrative console” on page 1268 for more information.
3. Associate a JASPI authentication provider with an application or specific web modules.

   During application deployment, the administrator or deployer can use the Map JASPI Provider option to associate web applications and specific web modules with an existing JASPI authentication provider as defined in the security configuration. This association can also be made when editing the options for an existing installed application. By default, an application inherits the JASPI settings defined in the WebSphere Application Server global or domain security configuration, and web modules inherit the application setting. The Map JASPI Provider option can be used to override these defaults. Read “Enabling JASPI authentication using the Map JASPI provider option during application deployment” on page 1270 for more information.

## Developing a custom JASPI authentication provider

You can develop a custom Java Authentication SPI for Containers (JASPI) authentication provider by creating classes that implement the required interfaces noted in the JSR 196: Java Authentication Service Provider Interface for Containers specification.

### Before you begin

Review the specific interface implementation requirements for JASPI authentication providers and modules in the JSR 196: Java Authentication Service Provider Interface for Containers specification.

## About this task

WebSphere Application Server supports the use of third-party authentication providers that are compliant with the servlet container profile specified in Java Authentication SPI for Containers (JASPI) Version 1.0.

The servlet container profile defines interfaces that are used by the security runtime environment in collaboration with the web container in WebSphere Application Server to invoke authentication modules before and after a web request is processed by an application. Authentication using JASPI modules is performed only when JASPI has been enabled in the security configuration and when a configured JASPI provider has been associated with the web module that processes the received web request.

To develop a custom authentication provider, create classes that implement the required interfaces noted in the JSR 196: Java Authentication Service Provider Interface for Containers specification. A provider can use one or more authentication modules for authentication. Modules can use callbacks to perform authentication, or they can manually add the necessary user identity information to the client subject. Depending on the scope of the provider, the implementation classes can be stored in various locations on the application server.

## Procedure

1. Create a class that implements the javax.security.auth.message.config.AuthConfigProvider interface.

   The AuthConfigProvider implementation class must define a public two-argument constructor and the getServerAuthConfig public method:

   ```
   import java.util.Map;
   import javax.security.auth.callback.CallbackHandler;
   import javax.security.auth.message.AuthException;
   import javax.security.auth.message.config.AuthConfigFactory;
   import javax.security.auth.message.config.AuthConfigProvider;
   import javax.security.auth.message.config.ServerAuthConfig;

   public class SampleAuthConfigProvider implements AuthConfigProvider {

           public SampleAuthConfigProvider(Map<String, String> properties, AuthConfigFactory factory) {
                   ...
           }
           public ServerAuthConfig getServerAuthConfig(String layer, String appContext, CallbackHandler handler)
                   throws AuthException {
                   ...
           }
   }
   ```

   An instance of the AuthConfigProvider implementation class is used by WebSphere Application Server when a request arrives to be processed by the web module of the application. The getServerAuthConfig method is used to obtain a ServerAuthConfig instance. The CallbackHandler argument in the method call is used by the authentication module(s).

2. Create a class that implements the javax.security.auth.message.config.ServerAuthConfig interface.

   The ServerAuthConfig implementation class must define the getAuthContextID and getAuthContext public methods:

   ```
   import java.util.Map;
   import javax.security.auth.Subject;
   import javax.security.auth.message.AuthException;
   import javax.security.auth.message.MessageInfo;
   import javax.security.auth.message.config.ServerAuthConfig;
   import javax.security.auth.message.config.ServerAuthContext;

   public class SampleServerAuthConfig implements ServerAuthConfig {

           public String getAuthContextID(MessageInfo messageInfo) throws IllegalArgumentException {
                   ...
           }
           public ServerAuthContext getAuthContext(String authContextID, Subject serviceSubject, Map properties)
   ```

```
                throws AuthException {
                ...
        }
}
```

The getAuthContextID and getAuthContext methods in the ServerAuthConfig implementation class are used to obtain a ServerAuthContext instance.

3. Create a class that implements the javax.security.auth.message.config.ServerAuthContext interface.

   The ServerAuthContext implementation class must define the validateRequest and secureResponse public methods:

```
import javax.security.auth.Subject;
import javax.security.auth.message.AuthException;
import javax.security.auth.message.AuthStatus;
import javax.security.auth.message.MessageInfo;
import javax.security.auth.message.config.ServerAuthContext;

public class SampleServerAuthContext implements ServerAuthContext {

        public AuthStatus validateRequest(MessageInfo messageInfo, Subject clientSubject, Subject serviceSubject)
                throws AuthException {
                ...
        }
        public AuthStatus secureResponse(MessageInfo messageInfo, Subject serviceSubject)
                throws AuthException {
                ...
        }
}
```

   The validateRequest method in the ServerAuthContext implementation class is used to invoke the module that authenticates the received web request message. If the authentication result is successful, the web container dispatches the received web request message that the target web module processes in the application. If the authentication result is not successful, the request is rejected with the appropriate response status.

4. Create a class that implements the javax.security.auth.message.module.ServerAuthModule interface.

   The ServerAuthModule implementation class must define the initialize, validateRequest, and secureResponse public methods:

```
import javax.security.auth.Subject;
import javax.security.auth.callback.CallbackHandler;
import javax.security.auth.message.AuthException;
import javax.security.auth.message.AuthStatus;
import javax.security.auth.message.MessageInfo;
import javax.security.auth.message.MessagePolicy;
import javax.security.auth.message.module.ServerAuthModule;

public class SampleAuthModule implements ServerAuthModule {

        public void initialize(MessagePolicy requestPolicy, MessagePolicy responsePolicy, CallbackHandler handler, Map options)
                throws AuthException {
                ...
        }

        public AuthStatus validateRequest(MessageInfo messageInfo, Subject clientSubject, Subject serviceSubject)
                throws AuthException {
                ...
        }

        public AuthStatus secureResponse(MessageInfo messageInfo, Subject serviceSubject)
                throws AuthException {
                ...
        }
}
```

   The initialize method in the ServerAuthModule implementation class is called by the ServerAuthContext implementation class to initialize the authentication module and to associate it with the ServerAuthContext instance.

   The validateRequest and secureResponse methods in this class are used respectively to authenticate the javax.servlet.http.HttpServletRequest and javax.servlet.http.HttpServletResponse contained in the javax.security.auth.message.MessageInfo that is received. These methods can use the CallbackHandler instance received in the initialize method to interact with the WebSphere security runtime to validate a user password, and the active user registry to retrieve a unique-id and

membership groups for a user. The retrieved data is placed in a Hashtable in the set of private credentials in the client subject. The WebSphere Application Server implementation of CallbackHandler supports three callbacks:

- CallerPrincipalCallback
- GroupPrincipalCallback
- PasswordValidationCallback

WebSphere Application Server expects the name values obtained with PasswordValidationCallback.getUsername() and CallerPrincipalCallback.getName() to be identical. If they are not, unpredictable results occur. The CallbackHandler's handle() method processes each callback given in the argument array of the method sequentially. Therefore, the name value set in the private credentials of the client subject is the one obtained from the last callback processed.

**Note:** Always use PasswordValidationCallback to validate a user password and to add the appropriate credentials to the client subject during authentication:

```
import javax.security.auth.Subject;
import javax.security.auth.callback.Callback;
import javax.security.auth.message.AuthException;
import javax.security.auth.message.AuthStatus;
import javax.security.auth.message.MessageInfo;
import javax.security.auth.message.callback.PasswordValidationCallback;

public AuthStatus validateRequest(MessageInfo messageInfo, Subject clientSubject, Subject serviceSubject)
       throws AuthException {
       ...
       PasswordValidationCallback pvcb = new PasswordValidationCallback(clientSubject, username, password);
       handler.handle(new Callback[] {pvcb});
       ...
}
```

If CallbackHandler is not used by the authentication module, and validateRequest returns a successful status, WebSphere Application Server requires that a Hashtable instance be included in the clientSubject with user identity information so that a custom login can be performed to obtain the credentials for the user. This Hashtable can be added to the client subject as in the following example:

```
import java.util.Hashtable;
import java.util.String;
import javax.security.auth.Subject;
import javax.security.auth.message.AuthException;
import javax.security.auth.message.AuthStatus;
import javax.security.auth.message.MessageInfo;
import com.ibm.wsspi.security.registry.RegistryHelper;
import com.ibm.wsspi.security.token.AttributeNameConstants.AttributeNameConstants;

public AuthStatus validateRequest(MessageInfo messageInfo, Subject clientSubject, Subject serviceSubject)
       throws AuthException {
       ...
       UserRegistry reg = RegistryHelper.getUserRegistry(null);
       String uniqueid = reg.getUniqueUserID(username);

       Hashtable hashtable = new Hashtable();
       hashtable.put(AttributeNameConstants.WSCREDENTIAL_UNIQUEID, uniqueid);
       hashtable.put(AttributeNameConstants.WSCREDENTIAL_SECURITYNAME, username);
       hashtable.put(AttributeNameConstants.WSCREDENTIAL_PASSWORD, password);
       hashtable.put(AttributeNameConstants.WSCREDENTIAL_GROUPS, groupList); //optional
       clientSubject.getPrivateCredentials().add(hashtable);
       ...
}
```

For more information about the Hashtable requirements and custom login, read about Developing custom login modules for a system login configuration for JAAS.

To support the login and authenticate methods of the Java Servlet 3.0 specification, the following logic must be added to the validateRequest method in the ServerAuthModule implementation class:

```
import java.util.Map;
import javax.security.auth.Subject;
import javax.security.auth.message.AuthException;
import javax.security.auth.message.AuthStatus;
import javax.security.auth.message.MessageInfo;
```

```
import javax.servlet.http.HttpServletRequest;

public AuthStatus validateRequest(MessageInfo messageInfo, Subject clientSubject, Subject serviceSubject)
       throws AuthException {
       ...
       Map msgMap = messageInfo.getMap();

       if ("login".equalsIgnoreCase(msgMap.get("com.ibm.websphere.jaspi.request"))) {
              // This request is for the login method
              String username = msgMap.get("com.ibm.websphere.jaspi.user");
              String password = msgMap.get("com.ibm.websphere.jaspi.password");
              // Authenticate using the user name and password set above.
       }
       else if ("authenticate".equalsIgnoreCase(msgMap.get("com.ibm.websphere.jaspi.request"))) {
              // this request is for the authenticate method
              String authHeader
                   = ((HttpServletRequest) messageInfo.getRequestMessage()).getHeader("Authorization");
              if (authHeader == null) {
                   // The user has not provided a username and password yet, return
                   // AuthStatus.SEND_CONTINUE to challenge
              }
              else {
                   // Authenticate using the user name and password in the authentication header.
              }
       }
       else {
              // This is not a Servlet 3.0 login or authenticate request; handle as usual.
       }
       ...
}
```

5. Compile all newly created classes.

   The following JAR files in your WebSphere Application Server installation must be specified in the class path to successfully compile the new classes:

   - *app_server_root*/dev/JavaEE/j2ee.jar
   - *app_server_root*/dev/was_public.jar (if any public WebSphere APIs were used)

6. Create a JAR file with the compiled classes.

   Depending on the requirements, the JAR file can be placed in one of three locations:

   - *app_server_root*/lib

     This location is always on the classpath for the WebSphere Application Server classloader. Using this location, the provider can be registered for a set of web modules or applications as the cell or domain default provider for all web modules and applications, and it can be registered manually as a persistent provider.

   - Shared library

     Place the provider JAR file anywhere on the WebSphere Application Server system. Configure a shared library that points to the JAR, and add that shared library to the application or server classpath. In a shared library, the provider can be registered for a set of web modules or applications, but the provider cannot be used as the cell or domain default provider. It also cannot be registered as a persistent provider because the shared library is not in the classpath for provider registration during server startup. For more information about configuring a shared library, read about Creating shared libraries.

   - Embedded in the application

     Include the provider JAR file in the application's EAR file as a utility JAR, or embed the compiled class files in the web module WAR. The embedded provider can be registered for the web modules in the application as long as the classes are included in the classpath for the web module. This provider cannot be used as a cell or domain default provider, nor can it be registered as a persistent provider. The classes in the application are not available for provider registration during server startup.

7. Configure the provider in the security configuration using the administrative console or an administration script.

Read about “Configuring a new JASPI authentication provider using the administrative console” for more information.

## Configuring a new JASPI authentication provider using the administrative console

You can configure a new Java Authentication SPI (JASPI) authentication provider in the cell or in the given security domain by using the administrative console.

### About this task

This release of WebSphere Application Server supports integration of message authentication providers that are compliant with the JASPI for Containers Version 1.0 specification.

When JASPI authentication providers are configured, and WebSphere Application Server receives an HTTP request message, the security runtime environment determines if the target application is configured to use JASPI authentication. If so, the runtime environment invokes the selected authentication provider to validate the received message. Otherwise, authentication of the message request is done according to the authentication mechanism provided by WebSphere Application Server for the appropriate messaging layer.

If you want to use JASPI message authentication services, you must supply an implementation of the required interfaces as defined in the JASPI specification. Read “Developing a custom JASPI authentication provider” on page 1263 for more information on these interfaces.

Authentication of HTTP request and response messages destined for JASPI-enabled deployed applications is performed according to the requirements of the Servlet Container Profile specified in the new specification.

**Note:** JASPI is supported in a mixed-cell environment, but can only be used in nodes that are version 8 or higher. Back-level nodes use existing authentication mechanisms.

To configure a new JASPI authentication provider using the administrative console, do the following:

### Procedure

1. Click **Security > Global security**.
2. Select **Enable Java Authentication SPI (JASPI)** to enable support for JASPI authentication.
3. Click **Providers**.

   **Note:** It is not necessary to select **Enable Java Authentication SPI (JASPI)** until after you have configured a new JASPI authentication provider.

   **Note:** The Default provider option is used to specify a single JASPI authentication provider to perform authentication for all web modules when JASPI authentication is enabled, and you do not override the web module to JASPI provider mapping during application deployment. During application deployment, you can override the default for every web module where it does not apply by choosing not to use JASPI or by naming a different provider to use for authentication. However, it is not recommended that you use this option unless you are certain that your default provider is capable of handling all types of web authentication (basic authentication, form authentication and client certificate authentication).
4. Click **New**.
5. Enter a name that uniquely identifies the JASPI authentication provider in the Provider name field.
6. Optional: Enter a textual description of the authentication provider in the Description field.
7. Enter the package-qualified name of the class that implements the authentication provider interface (javax.security.auth.message.config.AuthConfigProvider) in the Class name field.

**Note:** In the Message layer field, WebSphere Application Server Version 8.0 supports only the HttpServlet message layer profile as defined in the JASPI specification. You cannot change this value.

8. Optional: Under Custom Properties, click **New** if you require more than one property. This parameter is a list of key/value pairs.
9. Click **OK** or **Apply**.

### What to do next

You can also configure a new JASPI authentication provider by using **wsadmin** commands. Read JaspiManagement command group for the AdminTask object for more information.

Verify that your server has been restarted so that the changes to configure the JASPI provider will take effect.

## Modifying an existing JASPI authentication provider using the administrative console

You can modify and configure an existing Java Authentication SPI (JASPI) authentication provider in the cell or in the given security domain by using the administrative console.

### About this task

To modify and configure an existing JASPI authentication provider using the administrative console, do the following:

### Procedure

1. Click **Security > Global security**.
2. Click **Providers**. You also have the option to change the Default provider from the drop-down list.

   **Note:** You can modify the value of the **Enable Java Authentication SPI (JASPI)** checkbox to indicate whether or not JASPI support is enabled at a later time.
3. Select an existing JASPI authentication provider to modify.
4. Enter a textual description of the authentication provider in the Description field.
5. Enter a new package-qualified name of the class that implements the authentication provider interface (javax.security.auth.message.config.AuthConfigProvider) in the Class name field if you wish to change it.

   **Note:** In the Message layer field, WebSphere Application Server Version 8.0 supports only the HttpServlet message layer profile as defined in the JASPI specification. You cannot change this value.
6. Optional: Under Custom Properties, select an existing custom configuration property. Click **Delete** to remove the property, **Edit** to modify the property, or click **New** to create a new property. If you select **Edit** to modify an existing property, you can enter new values for the Name field and Value field if you wish to change them.
7. Click **OK** or **Apply**.

### What to do next

You can also modify an existing JASPI authentication provider by using **wsadmin** commands. For more information, read JaspiManagement command group for the AdminTask object.

Verify that your server has been restarted so that the changes to configure the JASPI provider will take effect.

## Deleting a JASPI authentication provider using the administrative console

You can delete an existing Java Authentication SPI (JASPI) authentication provider in the cell or in the given security domain by using the administrative console.

### About this task

To delete an existing JASPI authentication provider using the administrative console, do the following:

### Procedure

1. Click **Security** > **Global security**.
2. Click **Providers**, You can optionally select or deselect the **Enable Java Authentication SPI (JASPI)** check box.

   **Note:** You can modify the value of the **Enable Java Authentication SPI (JASPI)** checkbox to indicate whether or not JASPI support is enabled at a later time.
3. Select an existing JASPI authentication provider to delete.
4. Click **Delete**.

### What to do next

You can also delete a JASPI authentication provider by using wsadmin commands. For more information, read JaspiManagement command group for the AdminTask object.

Verify that your server has been restarted so that the changes to the JASPI provider configuration will take effect.

## Enabling JASPI authentication using the Map JASPI provider option during application deployment

An administrator or deployer can use the Map JASPI Provider option during application deployment to associate web applications and specific web modules with an existing Java Authentication SPI (JASPI) authentication provider as defined in the security configuration. This association can also be made when editing the options for a previously installed application.

### Before you begin

Before you perform this task, verify that a JASPI authentication provider is defined as part of the global or domain security configuration. Read about “Configuring a new JASPI authentication provider using the administrative console” on page 1268 for more information.

### About this task

By default, an application inherits the JASPI settings defined in the WebSphere Application Server global or domain security configuration, and web modules inherit the application setting. However, you can override these default values by using the Map JASPI Provider option during application deployment. Use this option to associate a specific JASPI provider from the global or domain security configuration with the entire application or with specific web modules. You can also use this option to specify that JASPI authentication not be used for an application or specific web module.

To associate a web application or specific web modules with an existing JASPI provider:

### Procedure

1. From the administrative console, click **Applications > New Application > New Enterprise Application**. Complete the required steps until you see the step for Map JASPI Provider, or click the **Map JASPI Provider** step from the installation options. A list containing the application name and associated web modules is displayed. To update a JASPI provider association after an application has

been deployed, click **Applications > Application Types > WebSphere enterprise applications**, and then select the application to be modified. Click **JASPI Provider** under the Detail properties.

2. Select the application or specific web module for which the JASPI provider setting is to be modified.
3. Click the **Select JASPI Provider** menu and select one of the following options:

   **Do not use JASPI**
   Select to disable JASPI authentication for the selected web module or for the application.

   **Inherit JASPI provider**
   Select to inherit the JASPI authentication settings from default values in the cell or domain security configuration, as appropriate.

   When **Inherit JASPI provider** is selected for a web module, JASPI authentication settings for the selected module are the settings that are specified for the application.

   When **Inherit JASPI provider** is selected for the application, JASPI authentication settings are the settings that are specified in the appropriate cell or domain security configuration.

   **Provider name**
   When a specific provider name is selected, that provider name is used to perform authentication of web requests for the selected application or web module.
4. Complete the remaining steps to finish installing and deploying the application.

### What to do next

Verify that your server has been restarted to ensure that the configuration changes to define the JASPI provider take effect. Read about “Configuring a new JASPI authentication provider using the administrative console” on page 1268 for more information.

## JASPI authentication providers collection

The Java Authentication Service Provider Interface (JASPI) for Containers Version 1.0 specification defines standard system programming interfaces that enable developers to write a pluggable custom authentication provider that can handle Java EE web authentication mechanisms as well as any extended authentication processing. The WebSphere Application Server runtime uses these standard system programming interfaces to invoke the JASPI authentication provider.

Read the Servlet Container Profile section in the JSR 196: Java Authentication Service Provider Interface for Containers specification for the requirements that third-party authentication providers must satisfy for more information.

If application security is enabled, and JASPI authentication is enabled with providers configured, when a web resource (such as a servlet or a JavaServer Page (JSP) file) is accessed, the security runtime checks if the web resource is mapped to a JASPI provider defined in the security configuration. If so, the runtime invokes the JASPI authentication provider to perform authentication for the HTTP request and response messages.

**Note:** WebSphere Application Server Version 8.0 supports only the HttpServlet message layer profile as defined in the JASPI specification.

To view this administrative console page, click **Security > Global security**. Under Authentication, click **Providers**.

To configure a new custom JASPI authentication provider in the cell or in the given security domain, click **New** and specify provider settings.

***Provider name:***

Specifies a name that uniquely identifies the authentication provider.

Select an existing custom JASPI authentication provider name to edit and configure it.

## JASPI authentication provider details

Use this page to provide configuration details for your custom Java Authentication SPI (JASPI) authentication service provider.

To view this administrative console page, click **Security > Global security**. Under Authentication, click **Providers**. Select an existing authentication service provider name or click **New** to create a new one.

***Provider name:***

Specifies a name that uniquely identifies the authentication provider.

***Description:***

Specifies a textual description of the authentication provider.

***Class name:***

Specifies the package-qualified name of the class that implements the authentication provider interface (javax.security.auth.message.config.AuthConfigProvider).

***Message layer:***

WebSphere Application Server Version 8.0 supports only the HttpServlet message layer profile as defined in the JASPI specification.

***Custom properties:***

Specifies additional custom properties needed to initialize the authentication provider. This parameter is a list of key/value pairs.

Click **Delete** to remove a custom property or **Edit** to modify a custom property.

## JASPI authentication enablement for applications

Use this page to enable or disable Java Authentication SPI (JASPI) authentication for an application or web module, and to specify the name of a JASPI authentication provider to be used for authenticating messages for the application or web module.

To view this administrative console page, click **Applications > Application Types > WebSphere enterprise applications**. Select an application, and under Detail Properties, select **JASPI provider**.

***Select JASPI provider:***

Select to indicate the web modules in the application that you wish to specify or to override the default JASPI authentication settings for.

Select one of the JASPI provider names to choose a provider to use to perform authentication of web requests for the selected Web module or the application.

To specify how JASPI authentication is performed for the selected web module or the application, choose one of the following:

**Do not use JASPI**
Select to disable JASPI authentication for the selected web module or for the application.

**Inherit JASPI provider**

Select to inherit the JASPI authentication settings from default values in the cell or domain security configuration, as appropriate.

When Inherit JASPI provider is selected for a web module, JASPI authentication settings for the selected module are the settings that are specified for the application.

When Inherit JASPI provider is selected for the application, JASPI authentication settings are the settings that are specified in the appropriate cell or domain security configuration.

**Provider name**

When a specific provider name is selected, that provider is used to perform authentication of web requests for the selected application or web module.

If JASPI authentication is enabled, and a specific provider name is not specified, then the default provider name is used. For more information, read about configuring a new JASPI authentication provider using the administrative console.

If JASPI authentication is disabled, or if no default provider is selected, JASPI authentication is not performed. Web authentication is then performed according to another authentication mechanism as selected in the cell or domain security configuration.

# Chapter 27. Developing Startup beans

This page provides a starting point for finding information about startup beans.

Startup beans allow business logic to run when an application starts or stops.

## Using startup beans

There are two types of startup beans: application startup beans and Module startup beans.

### About this task

**Note:** The capabilities provided with startup singleton session beans (EJB 3.1 specification) causes the WebSphere Application Server proprietary startup beans function to be deprecated.

A module startup bean is a session bean that is loaded when an EJB Jar file starts. Module startup beans enable Java Platform Enterprise Edition (Java EE) applications to run business logic automatically, whenever an EJB module starts or stops normally. An application startup bean is a session bean that is loaded when an application starts. Application startup beans enable Java EE applications to run business logic automatically, whenever an application starts or stops normally.

Startup beans are especially useful when used with asynchronous bean features. For example, a startup bean might create an alarm object that uses the Java Message Service (JMS) to periodically publish heartbeat messages on a well-known topic. This enables clients or other server applications to determine whether the application is available. Refer to the Enabling an application to wait for a messaging engine to start article if you are using the default JMS provider.

### Procedure

1. For Application startup beans, use the home interface, com.ibm.websphere.startupservice.AppStartUpHome, to designate a bean as an Application startup bean. For Module startup beans, use the home interface, com.ibm.websphere.startupservice.ModStartUpHome, to designate a bean as a Module startup bean.
2. For Application startup beans, use the remote interface, com.ibm.websphere.startupservice.AppStartUp, to define start() and stop() methods on the bean. For Module startup beans, use the remote interface, com.ibm.websphere.startupservice.ModStartUp, to define start() and stop() methods on the bean.

   The startup bean start() method is called when the module or application starts and contains business logic to be run at module or application start time.

   The start() method returns a boolean value. **True** indicates that the business logic within the start() method ran successfully. Conversely, **False** indicates that the business logic within the start() method failed to run completely. A return value of False also indicates to the Application server that application startup is aborted.

   The startup bean stop() methods are called when the module or application stops and contains business logic to be run at module or application stop time. Any exception thrown by a stop() method is logged only. No other action is taken.

   The start() and stop() methods must never use the TX_MANDATORY transaction attribute. A global transaction does not exist on the thread when the start() or stop() methods are invoked. Any other TX_* attribute can be used. If TX_MANDATORY is used, an exception is logged, and the application start is aborted.

   The start() and stop() methods on the remote interface use **Run-As** mode. **Run-As** mode specifies the credential information to be used by the security service to determine the permissions that a principal has on various resources. If security is on, the **Run-As** mode needs to be defined on all of the methods called. The identity of the bean without this setting is undefined.

© IBM Corporation 2009

There are no restrictions on what code the start() and stop() methods can run, since the full Application Server programming model is available to these methods.

3. Use an *optional* environment property integer, `wasStartupPriority`, to specify the start order of multiple startup beans in the same Java Archive (JAR) file. If the environment property is found and is the wrong type, application startup is aborted. If no priority value is specified, a default priority of `0` is used. It is recommended that you specify the priority property. Beans that have specified a priority are sorted using this property. Beans with numerically lower priorities are run first. Beans that have the same priority are run in an undefined order. All priorities must be positive integers. Beans are stopped in the opposite order to their start priority. The priority values for module startup beans and application startup beans are mutually exclusive. All modules will be started prior to the application being declared as "started" and therefore the start() methods for module startup beans within an application will be invoked prior to the start() methods for any application startup beans. Likewise, all application startup bean stop() methods for a specific Java Archive (JAR) file will be invoked prior to any module startup bean stop() methods for that JAR.
4. For module startup beans, the order in which EJB modules are started can be adjusted via the "Starting weight" value associated with each module
5. To control who can invoke startup bean methods via WebSphere Security do the following:
   a. Define the method permissions for the Start() and Stop() methods as you would for any EJB module. (See "Defining method permissions for EJB modules".)
   b. Ensure that the user that is mapped to the Security Role defined for the startup bean methods is the same user that is defined as the Server user ID within the User Registry.

### What to do next

View the startup beans service settings.

## Enabling startup beans in the administrative console

Enabling startup beans in the administrative console enables Java 2 Platform Enterprise Edition (J2EE) applications to run business logic automatically, whenever an application starts or stops normally.

### About this task

Use the following steps to enable startup beans in the administrative console.

### Procedure

1. Start the administrative console.
2. Select **Servers** > **Application Servers** > *server_name* > **Container Services** > **Startup beans service**.
3. Select the **Enable service at server startup** check box.
4. Click **Apply** to save the configuration.

### What to do next

View the startup beans service settings.

## Startup beans service settings

Use this page to enable startup beans that control whether application-defined startup beans function on this server. Startup beans are session beans that run business logic through the invocation of start and stop methods when applications start and stop. If the startup beans service is disabled, then the automatic invocation of the start and stop methods does not occur for deployed startup beans when the parent application starts or stops. This service is disabled by default. Enable this service only when you want to use startup beans. Startup beans are especially useful when used with asynchronous beans.

**Note:** The capabilities provided with startup singleton session beans (EJB 3.1 specification) causes the WebSphere Application Server proprietary startup beans function to be deprecated.

To view this administrative console page, click **Servers > Server types > WebSphere application servers >** *server_name*. Under **Container Settings**, expand **Container Services** then click **Startup beans service**.

## Enable service at server startup

Specifies whether the server attempts to initiate the startup beans service.

**Default**
Cleared

**Range**

**Selected**
When the application server starts, it attempts to initiate the startup bean service automatically.

**Cleared**
The server does not try to initiate the startup beans service. All startup beans do not start or stop with the application. If you use startup beans on this server, then the system administrator must start the startup beans service manually or select this property, and then restart the server.

# Chapter 28. Developing Service integration

This page provides a starting point for finding information about service integration.

Service integration provides asynchronous messaging services. In asynchronous messaging, producing applications do not send messages directly to consuming applications. Instead, they send messages to destinations. Consuming applications receive messages from these destinations. A producing application can send a message and then continue processing without waiting until a consuming application receives the message. If necessary, the destination stores the message until the consuming application is ready to receive it.

## Programming mediations

Several distinct tasks are involved in programming a mediation. Typically, the mediation code is written by a programmer, and is then deployed and administered by an integrator.

### Before you begin

Code examples for writing a mediation are provided in the following topic: “Adding mediation function to handler code” on page 1281.

The following application programming interfaces are provided for you to work with messages:

- You can use the SIMessage API to manipulate the contents of the message.
- You can use the SIMediationSession API to access the service integration bus so that your mediation can send and retrieve messages.

You can deploy mediations by using tooling such as the Rational Application Developer tools.

### About this task

The tasks for programming a mediation are as follows:

**Developing**
Writing a mediation by adding functional code to a mediation handler.

**Deploying**
Adding a mediation to a mediation handler list, and deploying it.

**Administering**
Associating a mediation handler with a destination (optional), and configuring the parameters to be used by the mediation handler at run time.

Take the following steps to program a mediation:

### Procedure

1. Create a mediation handler. For more information, see “Writing a mediation handler” on page 1280.
2. Add mediation function code to your mediation handler. For more information, see “Adding mediation function to handler code” on page 1281.
3. Working with the message payload, for example for logging messages within a mediation. For more information, see “Working with the message payload” on page 1288.
4. Use the Rational Application Developer tools to create a handler list, add your mediation handler to the list, and deploy the handler list as an Enterprise Archive (EAR file). See the Rational Application Developer information center for information about how to do this.

# Serializing the content of SIMessage

Use this task to convert an SIMessage object to a byte array.

## About this task

If you want to save an SIMessage object in your local file system or in a database, you must first convert the object to a byte array and format string. You can reconstruct the message from the byte array and format string. To do this, complete the following steps.

## Procedure

1. In your application program, record the format string associated with the SIMessage instance. For example:

   ```
   String savedFormat=message.getFormat();
   ```

2. Call the `getDataGraphAsBytes`. For example:

   ```
   Bytes newDataGraph = message.getNewDataGraph(newFormat);
   ```

   This method returns a copy of the payload as a byte stream. You can store the bytes and the associated format string, as you require.

3. To reconstruct the message, call the method `createDataGraph` provided by the SIDataGraphFactory API. This method requires a byte array and a format string. For example:

```
DataGraph newDataGraph = SIDataGraphFactory.getInstance().createDataGraph(byteArray, newFormat);
```

   This method creates a new data graph by parsing the bytes according to the format passed to the method.

## What to do next

You can use the newly created datagraph as the payload of an SIMessage instance by using the SIMessage setDataGraph() method. For example:

```
newMessage.setDataGraph(newDataGraph, savedFormat);
```

# Writing a mediation handler

You can write a mediation handler, add mediation function to it, and prepare it for installation on an application server.

## Before you begin

You should have access to a Java programming environment, and an assembly tool such as IBM Rational Application Developer.

## About this task

A mediation handler can be deployed. Each mediation handler executes some specific message processing at run time, for example transforming a message format, or routing a message to a particular destination. A mediation handler is a Java program framework, to which you add the code that performs the mediation function.

You can define a mediation handler class either in a Java project or an EJB project (which is needed for the deployment artifact). Your programming and deployment artifacts can be separated in different projects. The steps below are for an EJB project, but the steps are very similar if you want to create a Java project, because you define a target server for either a Java project or an EJB project and the server runtime plug-in sets the class path correctly.

## Procedure

1. Create a new EJB project:
   a. Switch to the Java EE perspective to work with Java EE projects. Click **Window > Open Perspective > Other > Java EE**.
   b. From the File menu, select **New > Project**.
   c. Expand the Java EE folder, and select Enterprise Application Project. Click **Next**.
   d. Optional: If you have created a Java project instead of an EJB project, right click on the Java project folder icon for the context menu and select Properties. When the Properties panel appears, select the Server properties and target the project to an appropriate server for your system, as in the next step.
   e. Enter a name for the project and target the project to an appropriate server for your system. (If this is the first time you target this server, click **New...**.) Click **Next** to take you to the EAR Module Projects window.
   f. Click **New Module...**.
   g. Create a new module project by selecting the check box against EJB project, and entering the name of your mediation handler.
   h. Click **Finish**. You are returned to the EAR Module Projects window.
   i. Click **Finish** to create the new project.
2. Create a mediation handler class by implementing the `com.ibm.websphere.sib.mediation.handler.MediationHandler` interface.
   a. From the File menu, select **New > Java Class**.
   b. Specify the source folder for your mediation EAR project.
   c. Specify a name for your mediation handler.
   d. Select Superclass `java.lang.Object`.
   e. Select Interface `com.ibm.websphere.sib.mediation.handler.MediationHandler`.
   f. Select the **Inherited abstract methods** check box.
   g. Click **Finish** to create the new mediation handler class.
3. Add functional code that transforms or routes messages to your mediation handler by using the IBM Rational Application Developer. For more information, see “Adding mediation function to handler code.” Beware that the default return value for the handle method created by the toolkit is `false`, which causes the message to be discarded. You must change the return value to `true` to preserve the message.
4. Generate an EAR file from your mediation handler class. Follow the instructions in the IBM Rational Application Developer documentation.

## What to do next

Next, you are ready to install the EAR file containing your mediation handler into the application server.

# Adding mediation function to handler code

A mediation handler is a wrapper for the mediation code that operates on the message. You can add mediation function to an existing mediation handler by working with the message context, the message properties, the message header or the message payload.

## Before you begin

Create or open a mediation handler in an EJB project. For more information, see “Writing a mediation handler” on page 1280.

## About this task

There are four main aspects of the message through which you can change the behavior of the mediation handler code, or influence the routing of a message. You can change the values in the message context and message properties, and you can work with the contents of the message (called the message payload), or with the message header:

- “Working with the message context”
- “Working with message properties” on page 1283
- “Working with the message header” on page 1284
- “Working with the message payload” on page 1288

## Example: Using mediations to trace, monitor and log messages

The most straightforward use of a mediation is for tracing, monitoring or logging messages that pass through a destination or topics spaces. This type of mediation does not modify the message; it only extracts information from the message and saves or displays the information elsewhere.

For example, the following mediation handler displays the API message and correlation IDs for each message it is sent:

```
public boolean(MessageContext context)
{
  SIMessageContext   msgCtx  = (SIMessageContext)context;
  SIMediationSession session = msgCtx.getSession();
  SIMessage          msg     = msgCtx.getMessage();
  String             msgId   = msg.getApiMessageId();
  String             corrId  = msg.getCorrelationId();
  String             dest    = session.getDestinationName();

  System.out.println(msgId+" (correlation id="+corrid) is passing through "+dest+".");

  return true;
}
```

## Working with the message context

You can work with the message properties to affect the way a message is mediated.

### Before you begin

Before you start this task, you should read about how information is carried in the mediation context in Mediation context information

### About this task

Interface SIMessageContext has a superinterface MessageContext. Methods in MessageContext allow you to manage a set of message properties, which enable handlers in a handler chain to share processing-related state. Most importantly, you can get the value of a specific property from the MessageContext by using the method getProperty, and you can set the name and value of a property associated with the MessageContext by using the method setProperty. You can also view the names of the properties in this MessageContext and remove a property (that is, a name-value pair) from the MessageContext.

At mediation runtime, all of the user-defined properties that have been set during configuration for the current mediation (see Configuring mediation context properties) are applied to the MediationContext property set.

### Procedure

1. Locate the point in your mediation handler where you insert the functional mediation code, in the method `handle (MessageContext context)`. As you are working with the MessageContext methods that give you access to message properties, you do not have to cast the interface to SIMessageContext **unless** you are also interested in the methods provided by SIMessageContext.
2. Get the SIMessage from the MessageContext object. For example, `SIMessage message = ((SIMessageContext)context).getSIMessage();`
3. Retrieve or set properties, by using the MessageContext methods. For instance, if a property has been defined during configuration with the name streetName, the type String, and the value "Main Street" your code to retrieve and print the street name might look like this:

### Example

```
public boolean handle(MessageContext context) throws MessageContextException {

   ........
  {
    /* Retrieve the street name property */
    String myStreetName;
    myStreetName = (String) getProperty(streetName);

    /* Display property value */
    System.out.println(myStreetName);

  }
}
```

## Working with message properties

You can work with the message properties to affect subsequent processing.

### Before you begin

Before you start this task, you should read about the properties that are supported by the SIMessage interface in ../ae/rjp0023_.dita.

### About this task

There are two different types of message properties:

- System properties (including JMS headers, JMSX properties, and JMS_IBM_properties)
- User properties.

You can work with message properties to affect which messages a later mediation should process, or to affect processing by a downstream application or mediation. The rule set in the selector field during mediation configuration tests values in the message properties.

You can access, modify and clear properties by using the SIMessage interface (see “SIMessage” on page 1292.) There are three different sets of methods:

- These properties operate on system properties, plus user properties if the name is qualified with a prefix `user.`:
  - getMessageProperty
  - setMessageProperty
  - deleteMessageProperty
  - clearMessageProperties
- These properties operate on user properties only, without the need for the prefix `user.`:
  - getUserProperty

  - setUserProperty
  - deletUserProperty
  - clearUserProperties
- getUserPropertyNames returns a list of the names of the user properties in the message.

Typically, you can work with message properties in the following way, when programming a mediation:

### Procedure

1. Locate the point in your mediation handler where you insert the functional mediation code, in the method `handle (MessageContext context)`. The interface is MessageContext, and you should cast this to SIMessageContext **unless** you are only interested in the methods provided by MessageContext.
2. Get the SIMessage from the MessageContext object. For example, `SIMessage message = ((SIMessageContext)context).getSIMessage();`
3. Build your mediation header function in a similar way to these examples, by using the reference information in ../ae/rjp0023_.dita to help:
   a. Get a user property of the message. For instance, `String task = (String)msg1.getUserProperty("task");`. In this case, the task string might refer to an operation that the mediation should perform.
   b. Set a user property, where message Properties are stored as name-value pairs. The setUserProperty method might only be used to set user properties, so the name passed into the method should not include the "user." prefix. For example, `msg1.setUserProperty("background","green");`
   c. Delete a user property from the message. For instance, `msg1.deleteUserProperty("task");`

### Example

Mediation function code to work with message properties might look similar to the code snippet in this example:

```
String task = (String)msg1.getUserProperty("task");
if (task != null) {
  if (task.equals("addColor")) {
    msg1.setMessageProperty(SIProperties.JMS_IBM_Format, "colorful");
    msg1.setUserProperty("background","green");
    msg1.setUserProperty("foreground","purple");
    msg1.setUserProperty("depth",new Integer(3));
    msg1.deleteUserProperty("task");
  }
  else {
    msg1.clearUserProperties();
  }
}
```

## Working with the message header

You can add function to a preexisting mediation handler to operate on the message header.

### Before you begin

Create or open a basic mediation handler in an EJB project (see “Writing a mediation handler” on page 1280. It is useful to have understood the elements of the task “Working with the message payload” on page 1288, because some of those elements are used in this task

### About this task

There are different types of field that you can set in message headers. Importantly, you can set the forward and return routing addresses for messages after they have been mediated at the current

destination. In addition there are other fields that you can set, such as priority and reliability for the message and its reply, and the remaining time before the message (or the reply) expires.

## Procedure

1. To set routing addresses in the message header, see “Setting routing addresses in a message header.”
2. To set all other fields in the message header, see “Working with non-routing path fields in a message header” on page 1287.

### *Setting routing addresses in a message header:*

You can add function to a pre-existing mediation handler to set routing addresses in the message header.

#### Before you begin

Before you start this task, you should have created the basic mediation handler in an EJB project (see “Writing a mediation handler” on page 1280.

#### About this task

To work with routing addresses, you will use the SIDestinationAddress and SIDestinationAddressFactory APIs. The SIDestinationAddress is the public interface that represents an service integration bus, and gives your mediation access to the name of the destination and the bus name. SIDestinationAddressFactory enables you to create a new SIDestinationAddress to represent an service integration bus destination. For reference information about these APIs, see “SIDestinationAddress” on page 1286 and “SIDestinationAddressFactory” on page 1287.

#### Procedure

1. Locate the point in your mediation handler where you insert the functional mediation code, in the method `handle (MessageContext context)`. The interface is MessageContext, and you should cast this to SIMessageContext **unless** you are only interested in the methods provided by MessageContext.
2. Get the SIMessage from the MessageContext object. For example:
   ```
   SIMessage message = ((SIMessageContext)context).getSIMessage();
   ```
3. Build your mediation header function by using these basic steps:
   a. Get a handle to the runtime environment. For example:
      ```
      .... SIMediationSession mediationSession = mediationContext.getSession();
      ```
   b. Create a forward routing path to set on the cloned object. For example, use the Vector class to create a extendable array of objects.
   c. Get the SIDestinationAddressFactory that is to be used for creating SIDestinationAddress instances. For example:
      ```
      SIDestinationAddressFactory destFactory = SIDestinationAddressFactory.getInstance();
      ```
   d. Create a new SIDestinationAddress, representing a service integration bus destination. For example:
      ```
      SIDestinationAddress dest = destFactory.createSIDestinationAddress(remoteDestinationName(),false);
      ```
      In this case, the second parameter, the Boolean “false”, indicates that the destination should not be localized to the local messaging engine, but can be anywhere on the service integration bus.
   e. Use the add method of the Vector class to add another destination name to the array.
   f. Clone the message, and modify the forward routing path in the cloned message. For example:
      ```
      clonedMessage.setForwardRoutingPath(forwardRoutingPath);
      ```
   g. Send the cloned message by using the send method in the SIMediationSession interface to send the message to the service integration bus. For example, if named "clonedMessage":

```
      mediationSession.send(clonedMessage, false);
```

4. Return *true* to ensure the message passed into the handle method of the MediationHandler interface continues along the handler chain.

**Example**

The complete mediation function code to change the forward routing path might look like this example:

```
/* A sample mediation that clones a message
 * and sends the clone off to another destination  */

public class RoutingMediationHandler implements MediationHandler {

 public String remoteDestinationName="newdest";

 public boolean handle(MessageContext context) throws MessageContextException {
  SIMessage clonedMessage = null;
  SIMessageContext mediationContext = (SIMessageContext) context;
  SIMessage message = mediationContext.getSIMessage();
  SIMediationSession mediationSession = mediationContext.getSession();

  // Create a forward routing path that will be set on the cloned message
  Vector forwardRoutingPath = new Vector();
  SIDestinationAddressFactory destFactory =
        SIDestinationAddressFactory.getInstance();
  SIDestinationAddress dest =
        destFactory.createSIDestinationAddress(remoteDestinationName,false);
  forwardRoutingPath.add(dest);

  try {
   // Clone the message
   clonedMessage = (SIMessage) message.clone();
   // Modify the forward routing path for the clone
   clonedMessage.setForwardRoutingPath(forwardRoutingPath);
   // Send the message to the next destination in the frp
   mediationSession.send(clonedMessage, false);
  } catch (SIMediationRoutingException e1) {
   e1.printStackTrace();
  } catch (SIDestinationNotFoundException e1) {
   e1.printStackTrace();
  } catch (SINotAuthorizedException e1) {
   e1.printStackTrace();
  } catch (CloneNotSupportedException e) {
   // SIMessage should clone OK so you shouldn't need to enter this block
   e.printStackTrace();
  }
  // allow original message to continue on its path
  return true;
 }
```

*SIDestinationAddress:*

The SIDestinationAddress public interface represents a service integration bus destination.

The API has three methods:

- isTemporary: This method determines whether the SIDestinationAddress represents a temporary or permanent Destination, returning a Boolean value.
- getDestinationName: Method to retrieve the name of the Destination represented by this SIDestinationAddress.

- getBusName: Method to retrieve the bus name of the Destination represented by this SIDestinationAddress.

For more information about the SIDestinationAddress interface, see the SIDestinationAddress generated API information.

*SIDestinationAddressFactory:*

The SIDestinationAddressFactory public interface extends java.lang.Object, and creates an SIDestinationAddressFactory at static initialization that is subsequently used for the creation of all instances of SIDestinationAddress.

The interface has three methods:
- getInstance: This method gets the singleton SIDestinationAddressFactory that is used for creating SIDestinationAddress instances.
- createSIDestinationAddress: These two methods are used to create a SIDestinationAddress to represent a service integration bus destination. The first will create a SIDestination that exists only on the local service integration bus (and maybe localized to the "local" messaging engine depending on the localOnly flag). The second method is used to create a SIDestination that exists on a remote service integration bus.
-

For more information about the SIDestinationAddressFactory interface, see the SIDestinationAddressFactory generated API information.

***Working with non-routing path fields in a message header:***

You can work with fields in a message header that identify and affect the behavior of messages.

**About this task**

In addition to the routing fields (see “Setting routing addresses in a message header” on page 1285), there are a number of fields in the message header that you can work with. These fields affect important qualities and characteristics of the message, such as priority and reliability, identity, and so on. See “Message header information” for information about the equivalence of the header fields to JMS message header fields, and the methods available to work with them.

**Procedure**

1. Locate the point in your mediation handler where you insert the functional mediation code, in the method `handle (MessageContext context)`. The interface is MessageContext, and you should cast this to SIMessageContext **unless** you are only interested in the methods provided by MessageContext.
2. Get the SIMessage from the MessageContext object. For example, `SIMessage message = ((SIMessageContext)context).getSIMessage();`
3. Build your mediation header function in a similar way to these examples, and using the reference information in “Message header information” to help:
   a. Set the reliability of the message. For instance, `siMessage.setReliability(Reliability.ASSURED_PERSISTENT);`. In this case, the quality of service is set to the highest level.
   b. Set the time to live for a message - that is, the time, in milliseconds, that the message is allowed to remain on a queue before it is removed if it is not processed. For example, `siMessage.setRemainingTimeToLive(1000000);` will set the remaining time before the message should expire to 1000 seconds.

*Message header information:*

The non-routing SIMessage header fields, and the methods available to work with them, can be mapped to JMS message header fields.

### Header fields

*Table 158. Mapping of SIMessage header fields to JMS message header fields. The first column of the table lists the SIMessage header fields. The second column provides a brief description of the fields. The third column provides the corresponding JMS message header fields. The fourth column lists the SIMessage methods.*

| SIMessage header field | Field description | Corresponding JMS message header field | SIMessage methods |
|---|---|---|---|
| Priority (ReplyPriority) | Integer value 0-9, higher value is higher message priority | JMSPriority (integer) | • getPriority<br>• setPriority<br>• getReplyPriority<br>• setReplyPriority |
| Reliability (ReplyReliability) | Specifies the reliability of message delivery. See ../ae/cjj9000_.dita for a description of the allowed values. | JMSDeliveryMode (string) supports two levels of reliability: PERSISTENT and NON_PERSISTENT | • getReliability<br>• setReliability<br>• getReplyReliebility<br>• setReplyReliability |
| TimeToLive (ReplyTimeToLive, RemainingTimeToLive) | An integer that represents the time in milliseconds that a message can remain on the queue before it expires. | JMSExpiration (long) is the time of expiry, calculated as "current time" plus (+) "time-to-live". | • getTimeToLive<br>• getReplyTimeToLive<br>• getRemainingTimeToLive<br>• setTimeToLive<br>• setReplyTimeToLive<br>• setRemainingTimeToLive |
| Discriminator (ReplyDiscriminator) | A string that contains a topic name that is tested by a selector rule to determine if the message should be mediated. | No corresponding JMS field | • getDiscriminator<br>• setDiscriminator<br>• getReplyDiscriminator<br>• setReplyDiscriminator |
| RedeliveredCount | Read-only field (integer) that holds that counts each time a message is re-delivered. | JMSRedelivered (Boolean) indicates that it is likely, but not guaranteed, that the message was delivered but unacknowledged in the past. | getRedeliveredCount |
| ApiMessageId | A string that uniquely identifies each message sent. | JMSMessageId (string) | • getApiMessageId<br>• setApiMessageId |
| CorrelationId | A string that links two messages, typically linking a request message with its response. | JMSCorrelationId (string) | • getCorrelationId<br>• setCorrelationId |
| UserId | A string that represents the identity of the user sending the message. | JMSX Userid is a message property not used by WebSphere Application Server. | • getUserId<br>• setUserId |

## Working with the message payload

You can work with the message payload in a pre-existing mediation handler, and transcode the message payload from one message format to another.

### Before you begin

Create or open a mediation handler in an EJB project. For more information, see “Writing a mediation handler” on page 1280. You should also read the tips for successfully programming mediations in the topic ../ae/cjy0115.dita.

## About this task

You can use this task to complete some or all of the following actions on the message payload:

- Locate the data objects within the message payload
- Convert the payload into another format
- Convert the payload into a byte array, for example if you want your mediation to log messages.

To work with the contents of a message, use the SIMessage and SIMessageContext APIs. Additionally, use SIMediationSession to provide your mediation with access to the service integration bus, to send and receive messages. For more information, see:

- ../ae/cjy0000.dita
- “MediationHandler” on page 1291
- “SIMessageContext” on page 1291

To work with specific fields within a message, use Service Data Objects (SDO) Version 1 data graphs. For more information, see SDO data graphs. For more information about the format of supported message types, and examples of how to work with them, see “Mapping of SDO data graphs for web services messages” on page 1298.

To work with the message payload, take the following steps:

## Procedure

1. Locate the point in your mediation handler where you insert the functional mediation code, in the method `handle (MessageContext context)`. The interface is MessageContext, and you should cast this to SIMessageContext unless you only want to work with the methods provided by MessageContext.
2. Retrieve the data graph of the message payload as follows:
   a. Get the SIMessage from the MessageContext object. For example:
      ```
      SIMessage message = ((SIMessageContext)context).getSIMessage();
      ```
   b. Get the message format string to determine its type. For example:
      ```
      String messageFormat = message.getFormat();
      ```
   c. Retrieve the DataGraph object from the message. For example:
      ```
      DataGraph dataGraph = message.getDataGraph();
      ```

      For more information, see SDO data graphs.
3. Optional: Locate data objects within the payload:
   a. Navigate within the graph to a named DataObject. For example, where DataObject has the name "data":
      ```
      DataObject dataObject = dataGraph.getRootObject().getDataObject("data");
      ```
   b. Retrieve information contained in the data object. For example, if the message is a text message:
      ```
      String textInfo = dataObject.getString("value");
      ```
4. Work with the fields within the message. For an example of how to do this, see “Example code for message fields” on page 1290.
5. Optional: Transcode the payload into another format:
   a. Review the topic “Transcoding between message formats” on page 1293 to understand the implications of transcoding the payload.
   b. Call the method getNewDataGraph, passing the new format as a parameter, which returns a copy of the payload in the new format. For example:
      ```
      DataGraph newDataGraph = message.getNewDataGraph(newFormat);
      ```
   c. Write the data graph in the new format back to the message using the setDataGraph method. For example:

```
message.setDataGraph(newDataGraph, newFormat);
```

6. Optional: Convert the payload into a stream of bytes:
   a. Review the topics “Transcoding a message payload into a byte array” on page 1295 and “Transcoding a byte array into a message payload” on page 1296 to understand the implications of converting between message format and byte stream, and back again.
   b. Call the method getDataGraphAsBytes, which returns a copy of the payload as a byte stream. For example:
      ```
      byte[] newByteArray = message.getDataGraphAsBytes();
      ```
   c. Call the method createDataGraph provided by the SIDataGraphFactory API, which creates a new data graph by parsing the bytes according to the format passed to the method. For example:
      ```
      DataGraph newDataGraph = SIDataGraphFactory.getInstance().createDataGraph( byteArray, format);
      ```
   d. Work with the message as a stream of bytes. For an example of how to do this, see “Example code for message fields”
7. Return *True* in your mediation code so that the MessageContext is passed to the next mediation handler in the handler list. If the return value is *False* the MessageContext will be discarded and will not be delivered to the destination.

   **Note:** If your mediation handler is the last handler in the handler list, and the forward routing path is empty, the message is made available to consuming applications on that destination. If the forward routing path not empty, the message is not made available to any consumers on that destination. Instead, the message is forwarded to the next destination in the routing path.

### Example code for message fields

Below is an example of the code for a mediation for working with a field in a message:

```
public boolean handle(MessageContext context) throws MessageContextException {

 /* Get the SIMessage from the MessageContext object */
 SIMessage message = ((SIMessageContext)context).getSIMessage();

 /* Get the message format string */
 String messageFormat = message.getFormat();

 /* If you have a JMS TextMessage then extract the text contained in the message. */
 if(messageFormat.equals("JMS:text"))
 {
  /* Retrieve the DataGraph object from the message */
  DataGraph dataGraph = message.getDataGraph();

  /* Navigate down the DataGraph to the DataObject named 'data'. */
  DataObject dataObject = dataGraph.getRootObject().getDataObject("data");

  /* Retrieve the text information contained in the DataObject. */
  String textInfo = dataObject.get("value");

  /* Use the text information retrieved */
  System.out.println(textInfo);
 }

 /* Return true so the MessageContext is passed to any other mediation handlers
 * in the handler list */
 return true;

 }
```

The complete mediation function code for working with the message payload as a stream of bytes might look like this example:

```
  public boolean handle(MessageContext context)throws MessageContextException {

  /* Get the SIMessage from the MessageContext object */
  SIMessage message = ((SIMessageContext)context).getSIMessage();

    if (!SIApiConstants.JMS_FORMAT_MAP.equals(msg.getFormat()))
    {
      try
      {
        dumpBytes(msg.getDataGraphAsBytes());
      }
      catch(Exception e)
      {
        System.out.println("The message contents could not be retrieved due to a "+e);
      }
    }
    else
    {
      System.out.println("The bytes for a JMS:map format message cannot be shown.");
    }

    return true;
  }

  private static void dumpBytes(byte[] bytes)
  {
    // Subroutine to dump the bytes in a readable form to System.out
  }
}
```

***MediationHandler:***

The public interface MediationHandler has just one method: handle. This method is used by the runtime to invoke a mediation.

The method handle is called by the runtime when a message is to be mediated. The method returns Boolean *True* if the message passed into this method should continue along the handler list, otherwise *False*.

At the end of the handler list, the message is sent to the next destination on the routing path, unless the forward routing path is empty, when the message is made available to consuming applications on the current destination.

For more information about the MediationHandler interface, see the MediationHandler generated API information.

***SIMessageContext:***

Public interface SIMessageContext extends javax.xml.rpc.handler.MessageContext. This is the object that is required on the interface of a mediation handler. In addition to the context information that might be passed from one handler to another, it can return a reference to an SIMessage and an SIMediationSession.

The SIMessage is the service integration technologies representation of the message being processed by the MediationHandler. The SIMediationSession is a handle to the runtime resources.

The interface MessageContext abstracts the message context that is processed by a handler in the handle method. The MessageContext interface provides methods to manage a property set. MessageContext properties enable handlers in a handler chain to share processing related state.

As well as defining the method that is invoked by the mediation runtime environment, the interface might also specify properties following the Enterprise JavaBeans naming pattern, or by providing a BeanInfo class. Each property of the bean will be initialized from a single environment entry with the same name as the property. Bean properties of simple type are specified by using Java Platform, Enterprise Edition (Java EE) env-entry. If the handler has properties that are of non-simple type, then other environment definitions may be used.

The API has two methods:

- The getSIMessage method to get the service integration bus representation of the message being mediated. Read more about the SIMessage API in "SIMessage."
- The getSession method to get an SIMediationSession object that is a handle to the runtime environment. Read more about the SIMediationSession API in "SIMediationSession" on page 1293.

*SIMessage:*

The SIMessage interface is the public interface to a service integration bus message for use by mediations and other service integration bus components. This interface extends java.lang.Cloneable and java.lang.Serializable.

The version of Service Data Objects (SDO) supported by mediations is Version 1.

The SIMessage interface has many methods allowing you to work with message properties, header contents, routing path, metadata, and others:

- The method getDataGraph returns the SDO data graph. This contains the SIMessage payload content in a tree representation. Using the data graph, you can work directly with individual fields in the message payload. For more information about SDO data graphs, see SDO data graphs.
- You can transcode a message payload by calling the method getNewDataGraph(format). It returns a copy of the payload in the new format. You can write the new datagraph back to the message by using setDataGraph(DataGraph, format). For more information, see "Transcoding between message formats" on page 1293.
- If you want to log a message as a simple byte stream, you can retrieve the message payload as a byte array by using the method getDataGraphAsBytes. For more information about converting from data graph to bytes, and back again, see "Transcoding a message payload into a byte array" on page 1295 and "Transcoding a byte array into a message payload" on page 1296.
- There are methods to get, set, delete and clear user properties and message properties. You can also retrieve a list of user property names. For more information about working with properties, see "Working with message properties" on page 1283.
- Forward and reverse routing paths define a sequential list of intermediate bus destinations through which messages pass to reach a target bus destination. You use a routing path to apply the mediations configured on several destinations to the messages sent along the path. The following methods allow you to get and set the contents of the ForwardRoutingPath and ReverseRoutingPath for an SIMessage:
  - getForwardRoutingPath()
  - setForwardRoutingPath()
  - getReverseRoutingPath()
  - setReverseRoutingPath()

  For more information about routing paths, see Destination routing paths. For information about how to work with routing addresses, see "Setting routing addresses in a message header" on page 1285.
- If your mediation changes the content of the message, there is a risk that the message is no longer valid. If the data graph is not valid, the message cannot be sent through the service integration bus or

stored in the message store. In this case, the message is not **well formed**. A message is well formed when all the values of the message properties might be serialized, and the data graph of the message conforms to the format of the message. You can test your message by using the method isWellFormed. It returns *true* when the message contains a well formed data graph. This test has implications for performance. For more information, see Setting tuning properties for a mediation.

- You can work with the time for the message to live, measured in milliseconds from the time when the message was originally sent:
  - The methods getTimeToLive and setTimeToLive allow you to get and set the value of the TimeToLive field in the message header. A value of 0 indicates that the message will never expire.
  - The methods getRemainingTimeToLive and setRemainingTimeToLive allow you to get the remaining time in milliseconds before the message expires, and set the remaining time in milliseconds before the message should expire.

For more information about SIMessage, see the API documentation.

*SIMediationSession:*

The SIMediationSession public interface defines the methods for querying and interacting with the service integration bus. As well as defining the methods for working with the service integration bus, this interface also includes methods that provide information about where the mediation is invoked from, and the criteria that are applied before the message is mediated.

Both selector and discriminator control which messages are sent to the mediation, through a rule specified in a text string. The rule specified by the selector examines the header and properties of the message, whereas the discriminator examines the topic of the message. If a message contains both selector and discriminator, it must match both rules for the message to be mediated. If either the selector or the discriminator rule does not match, the message is not mediated.

The API has these methods:

- getBusName returns the name of the bus upon which the mediation is associated.
- getDestinationName returns the name of the destination with which the mediation is associated.
- getDiscriminator returns the discriminator that is defined in the mediation definition.
- getMediationName returns the name of the mediation that is being executed.
- getMessageSelector returns the message selector that is defined in the mediation definition.
- getMessagingEngineName returns the name of the messaging engine from which the mediation was invoked
- getSIDestinationConfiguration returns the SIDestinationConfiguration object associated with the destination, specified by destinationName or destinationAddress.
- receive receives an SIMessage from the service integration bus. There are four variants.
- resetIdentity changes the identity of the given message to the current run-as identity.
- send sends a copy of an SIMessage to the service integration bus, in addition to the message returned by the message interface.

See also the generated API information for SIMessageContext.

***Transcoding between message formats:***

A mediation can convert a message from one format to another without changing the semantic meaning of the message. This operation is referred to as transcoding a message.

The following code is an example mediation handler that transcodes a message into a new message format, providing that the message can be transcoded:

```
private static final String NEW_FORMAT = "JMS:text";

public boolean(MessageContext context) throws MessageContextException
{
  try
  {
    SIMessageContext msgCtx  = (SIMessageContext)context;
    SIMessage        msg     = msgCtx.getMessage();
    DataGraph        newDg   = msg.getNewDataGraph(NEW_FORMAT);

    msg.setDataGraph(newDg,NEW_FORMAT);
    return true;
  }
  catch(Exception e)
  {
    // Reroute the original message to the exception destination
    MessageContextException mce =
      new MessageContextException("Unable to transcode to "+NEW_FORMAT",e);
    throw mce;
  }
}
```

The table below describes which messages can be transcoded, and gives the outcome for each format pairing. Note that the abbreviation DG represents "data graph". The numbers within brackets in the table are explained as follows:

- (1) A message with format JMS: cannot have a payload. It does not carry any message data other than the message properties. If a mediation calls `getDataGraph()` on a message with format JMS:, `null` is always returned. All other message formats must have a message payload. This means that a message with format JMS: cannot be transcoded into another format. If a mediation needs to change a message with format JMS: into a message with any other format, the mediation needs to call the methods `SIDataGraphFactory.getInstance().createDataGraph(newFormat)` and `setDataGraph` on the SIMessage object to change the message contents.
- (2) `null` is always returned if a mediation calls `getDataGraph()` on a message with format JMS:
- (3) A mediation can call the method getNewDataGraph() on a message to return a copy datagraph with the same format as the message. The copy can be edited, leaving the original message unchanged. For SOAP and Beans, you can change the message model by editing the format string to change the value that follows the ":".

*Table 159. Message transcoding. The table contains the different formats that can be used to convert the messages from one format to another. The table shows the transcoding options that is possible between the different formats, and it also provides the effect the conversion has on the messages.*

| | **To JMS:** | **To JMS:text** | **To JMS:bytes** | **To JMS:stream** | **To JMS:object** | **To SOAP:** | **To Bean:** |
|---|---|---|---|---|---|---|---|
| **From JMS:** | DG=null (1) | DG=null (1) | DG=null (1) | DG=null (1) | DG=null (1) | DG=null (1) | DG=null (1) |
| **From JMS:text** | DG=null (2) | Yes (3) | Yes, bytes contain UTF-8 | Yes, if text contains XML that conforms to the correct schema. | No | Yes, if message content is valid SOAP. | Yes, if message content is valid SOAP. |
| **From JMS:bytes** | DG=null (2) | Yes, but only when the bytes can correctly be interpreted as a UTF-8 string. | Yes (3) | Yes, if bytes contain XML that conforms to the correct schema. | Yes, assume that bytes are a serialized object. | Yes, if message content is valid SOAP. | Yes, if message content is valid SOAP. |
| **From JMS:stream** | DG=null (2) | Yes, text is XML transcoding. | Yes, bytes contain XML transcoding. | Yes (3) | No | No | No |

*Table 159. Message transcoding (continued). The table contains the different formats that can be used to convert the messages from one format to another. The table shows the transcoding options that is possible between the different formats, and it also provides the effect the conversion has on the messages.*

| | To JMS: | To JMS:text | To JMS:bytes | To JMS:stream | To JMS:object | To SOAP: | To Bean: |
|---|---|---|---|---|---|---|---|
| **From JMS:object** | DG=null (2) | No | Yes, bytes contain the object serialization. | No | Yes (3) | No | No |
| **From SOAP:** | DG=null (2) | Yes | Yes | No | No | Yes (3) - if message content matches the new WSDL. | Yes |
| **From Bean:** | DG=null (2) | Yes | Yes | No | No | Yes | Yes (3) - if message content matches the new WSDL. |

*XML schema definition for JMS stream messages:*

This is the XML schema definition for transcoding JMS stream messages to message types.

The following XML schema definition uses the target namespace http://www.ibm.com/xmlns/prod/websphere/messaging/jms/ to express JMS stream messages in XML. Use this definition to transcode between a byte array and a message payload.

```
<xsd:schema elementFormDefault="qualified" xml:lang="EN"
  targetNamespace="http://www.ibm.com/xmlns/prod/websphere/messaging/jms"
  xmlns="http://www.ibm.com/xmlns/prod/websphere/messaging/jms"
  xmlns:xsd="http://www.w3.org/2001/XMLSchema">

  <xsd:element name="data" type="StreamBody"/>

  <xsd:complexType name="StreamBody">
    <xsd:sequence>
      <xsd:element name="value"
        type="streamTypes"
        minOccurs="0"
        maxOccurs="unbounded"
        nillable="true"/>
    </xsd:sequence>
  </xsd:complexType>

  <xsd:simpleType name="character">
    <xsd:restriction base="xsd:string">
      <xsd:minLength value="1"/>
      <xsd:maxLength value="1"/>
    </xsd:restriction>
  </xsd:simpleType>

  <xsd:simpleType name="streamTypes">
   <xsd:union memberTypes="xsd:long xsd:int xsd:short xsd:byte xsd:boolean
            xsd:float xsd:double xsd:string xsd:hexBinary character"/>
  </xsd:simpleType>
</xsd:schema>
```

*Transcoding a message payload into a byte array:*

You can transcode the message payload into a byte array.

For example, you might want to write a mediation handler that logs a message as a simple byte stream. You can retrieve the message payload as a byte array by using the method getDataGraphAsBytes. The table below describes the rules for transcoding an SIMessage data graph into a byte array.

*Table 160. Rules for transcoding a message payload into a byte array. The first column of the table contains the datagraph formats used for transcoding a message into a byte array. The second column provides the preconditions for the datagraph format if available. The third column provides the result of the transcode. The fourth column contains the character set encodings if they are applicable for the messages.*

| Datagraph format | Pre-conditions | Outcome | Character set encoding |
|---|---|---|---|
| JMS: | None | Returns null. | Not applicable. |
| JMS:text | None | Returns the result of java.lang.String:getBytes(String charSetName) when applied to the `data/value` element of the graph, where charSetName = "UTF-8" | UTF-8 |
| JMS:bytes | None | Returns a copy of the value of the `data/value` element of the data graph for the message. | Not applicable. |
| JMS:stream | None | Returns a byte buffer containing an XML serialization of the stream message according to the XML schema for stream messages. | UTF-8 |
| JMS:object | None | Returns a copy of the value of the `data/value` element of the data graph for the message. | Not applicable. |
| SOAP: | If the byte array must be generated by this operation (instead of using an existing byte array available through lazy parsing) then the data graph must be valid with respect to the WSDL model. | Returns a byte buffer containing a SOAP serialization of the data graph. If the SOAP message contains an attachment, the buffer has the multipart MIME format. | Either UTF-8, or that of the source message for the graph, where logically equivalent to the graph state. |
| Bean: | The data graph must be valid with respect to the WSDL model. In the absence of a SOAP binding the serialization will be performed using RPC/literal encoding. | Returns a byte buffer containing a SOAP serialization of the data graph. If the Bean contains attachments then the buffer will be in multipart MIME format. | UTF-8 |

*Transcoding a byte array into a message payload:*

A mediation can transcode a byte array into a message payload without changing the meaning of the message.

A mediation can reconstruct the message payload from a byte array, for example after logging a message. To reconstruct the message, call the method `createDataGraph` provided by the SIDataGraphFactory API. This method requires a byte array and a format string and creates a new data graph by parsing the bytes according to the format passed to the method, as shown in the following example:

```
DataGraph newDataGraph = SIDataGraphFactory.getInstance().createDataGraph(byteArray, newFormat);
```

The table below describes the rules for transcoding a byte array into an SIMessage data graph.

*Table 161. Rules for transcoding a byte array into an SIMessage data graph. The first column of the table contains the format arguments used for transcoding a byte array into an SIMessage data graph. The second column provides the preconditions if available for the format arguments. The third column provides the resultant SIMessage data graphs for the specified format arguments.*

| Format argument | Pre-conditions | Outcome |
|---|---|---|
| JMS: | None | Returns null |
| JMS:text | `java.lang.String(inputBytes, "UTF-8")` does not result in an exception. | Returns new data graph instance of format JMS:text. Value of graph at path `data/value` has value equal to `java.lang.String(inputBytes, "UTF-8")`. |
| JMS:bytes | `inputBytes` is not null. | Returns new data graph instance of format JMS:bytes. Value of graph at path `data/value` is a copy of the `inputBytes` byte array. |
| JMS:stream | Byte array is XML, and is valid with respect to the `JmsStreamBody` type of the XML schema definition. | Returns new data graph instance of format JMS:stream. Value of graph at path `data/value` has type List, containing a sequence of simple typed values according to the types and values of each of the elements in the XML document. |
| JMS:object | Not null<br>**Note:** You must ensure that the byte array is a valid serialized object. | Returns new data graph instance of format JMS:object. Value of graph at path `data/value` is a copy of the `inputBytes` byte array. |
| SOAP: | The byte buffer contains valid SOAP with respect to the associated WSDL model. | Returns new data graph with type system defined by the WSDL referenced by the byte buffer, and values of the graph defined by the SOAP payload. |
| Bean: | The byte buffer contains valid Bean with respect to the associated WSDL model. | Returns new data graph with type system defined by the WSDL referenced by the byte buffer, and values of the graph defined by the Bean payload. |

*Web services messages overview:*

To work with the data graph form of web services messages, you need to know the structure of the data graph, and how to develop code that can navigate the data graph.

**The format of web services messages**

WebSphere Application Server (base) supports two formats for web services messages: SOAP and enterprise beans. (These are similar to Java APIs for XML based RPC, or JAX-RPC.)

To work with web services messages, you need the following information:

- The structure of the Service Data Objects (SDO) Version 1 data graphs for web services messages. See “Mapping of SDO data graphs for web services messages” on page 1298 for more information about the data elements and the shape of the data graph.
- Reference information to help you develop code to navigate the data graphs of the messages that your program mediates. See “Mapping XML schema definitions to the SDO type system” on page 1302.
- For XML representations of the shape of each part of web services messages, sample code snippets and further information about the data graph format, see:“Web Services code example” on page 1305.

### Format types

The web services message type is defined by a message format string within the message. The format string is prefixed with a domain identifier, which is either SOAP or Bean, followed by four comma-separated fields as shown below:

```
SOAP:<wsdlLocation>,<serviceNameSpace>,<serviceName>,<portName>
Bean:<wsdlLocation>,<serviceNameSpace>,<serviceName>,<portName>
```

The fields are described in the following table:

| Field name | Message format string | Field description |
|---|---|---|
| WSDL location | `<wsdlLocation>` | The URI where the WSDL for this message is located. The WSDL is deployed to the SDO repository, by using this location as the key. |
| Service namespace | `<serviceNamespace>` | Service namespace and Service name uniquely identify the Service definition within the WSDL. |
| Service name | `<serviceName>` | Service name and Service namespace uniquely identify the correct Service definition within the WSDL. |
| Port name | `<portName>` | Locates the Port definition within the Service, giving the PortType and Binding information that is required for message processing. |

*Mapping of SDO data graphs for web services messages:*

The structure of web services messages is described by the Service Data Objects (SDO) Version 1 data graphs for web services messages.

### Overall layout of a web services message

A web services message is described by a format string and three metadata fields: operationName, messageName, and messageType. The payload of the message is split across three other sections: headers, attachments and the body.

The Info node is the top of the SDO data graph for all web services messages. The following table describes the Info node properties and associated types.

| Property name | Property type | Property description |
|---|---|---|
| operationName | `java.lang.String` | Identifies the WSDL operation that is associated with the message. If the data access service cannot identify the message, this field is null. See “Identifying web services messages” on page 1299. |
| messageName | `java.lang.String` | Identifies the WSDL message that is associated with the message. If the data access service cannot identify the message, this field is null. See “Identifying web services messages” on page 1299. |

| | | |
|---|---|---|
| messageType | `java.lang.String` | Identifies WebService type of message instance. This field can have the values: *input*, *output*, *fault*, *ambiguous*. If the data access service cannot identify the message, this field is null. See “Identifying web services messages.” |
| headers | `java.util.List` of data objects. | Contains a list of header entry data objects. Each SOAP header in the message results in a header entry in this list. See “Message header layout ” on page 1300. |
| attachments | `java.util.List` of data objects. | Contains a list of attachment entry data objects. For SOAP messages with attachments, each MIME part in the message (except the MIME part containing the SOAP envelope) is mapped to an entry in this list. See “Message attachment layout” on page 1300. |
| body | `commonj.sdo.DataObject` | A nested data object, which represents the body of the SOAP envelope. See “Message body layout” on page 1301. |

**Identifying web services messages**

Processing of messages depends on whether the messages have WSDL definitions. The minimum amount of information required for processing without WSDL is "SOAP:". The minimum amount of information required for processing with WSDL is: "SOAP:location,namespace,service,port". If the format string does not include all five of these fields, the SOAP data access service attempts to process the message without WSDL.

- **Processing messages without WSDL definitions:** If the format string does not include full WSDL information, the SOAP data access service processes the message without attempting to match the message against definitions in WSDL. As a result, operationName and messageName are set to null, and messageType is set only when processing a fault message.
- **Processing messages with WSDL definitions:** If the format string includes <WSDL location>,<Service namespace>,<Service name>, and <Port name>, the SOAP and Beans data access services process the message by using the WSDL definitions of the service.

  **Note:** In either of the following circumstances, SOAP message processing fails after supplying all the required WSDL information:
  - the SOAP data access service fails to locate the WSDL
  - the WSDL fails to corroborate the message

When the SOAP data access service processes a SOAP request or reply message, it tries to match it against the message definitions in the WSDL. Usually there is one matching definition, and the operationName, messageName, and messageType are filled in appropriately. If there is more than one matching definition, the data access service selects a message definition, fills in the operationName and messageName. and sets the messageType to *ambiguous*.

When processing fault messages, identification is slightly different. In all cases the messageType is set to *fault*. If the message matches a unique fault definition in the WSDL, the operationName and messageName properties are also set.

### Message header layout

The list of headers has two types of entry, header entry or bound header entry, depending on whether the header is based on part of the message or not.

The header entry type is used to handle headers that meet either of the following criteria:

- the header is part of the message that is modeled in WSDL
- the header is part of the message that is not modeled in WSDL, but is based on a part of the message

For a model of this header, see “Header entry.”

The bound header entry type is used when the SOAP binding for the message has bound a part of the body into a MIME attachment. (This occurs when you use a <MIME:content> element to bind a part of the message to an attachment.) For consistent mediation programming, all of the body data is stored in the body node in the graph. Unlike the normal attachment entry, a bound attachment entry is placed into the attachments list. The bound attachment entry contains the MIME meta-data for the attachment and the name of the message part that contains the data taken from this attachment. This allows mediations designed to process attachments to locate the data in the body part of the data graph. For a model of this attachment see “Bound header entry.”

### Header entry

| Property name | Property type | Property description |
|---|---|---|
| mustUnderstand | `java.lang.Boolean` | Carries the value from the mustUnderstand attribute on the SOAP header, if present. |
| actor | `java.lang.String` | Carries the value from the actor attribute on the SOAP header, if present. |
| any | `commonj.sdo.Sequence` | Container for the contents of the SOAP header. |

### Bound header entry

| Property name | Property type | Property description |
|---|---|---|
| mustUnderstand | `java.lang.Boolean` | Carries the value from the mustUnderstand attribute on the SOAP header, if present. |
| actor | `java.lang.String` | Carries the value from the actor attribute on the SOAP header, if present. |
| messagePart | `java.lang.String` | Contains the name of the message part that carries the data from this message header. |

### Message attachment layout

Message attachments are handled in a similar way to headers, and instances of them populate the attachments list in the Info node.

There are two types of attachment entry to handle MIME attachments: attachment entry and bound attachment entry.

Attachment entry is for general attachments: see “Attachment entry” on page 1301.

Bound attachment entry includes <MIME:content> elements that bind a part of the body into a MIME attachment. If you are programming a mediation, you must know how to locate the data within the graph. For consistent mediation programming, the attachment data is placed in the message body, referred to by the part name in the header entry, which includes the other MIME metadata. For a model of this attachment, see “Bound attachment entry.”

### Attachment entry

| Property name | Property type | Property description |
|---|---|---|
| contentType | `java.lang.String` | Carries the contentType from the MIME part that is represented by the attachment entry. |
| contentTransferEncoding | `java.lang.String` | Carries the contentTransferEncoding from the MIME part that is represented by the attachment entry. |
| contentId | `java.lang.String` | Carries the contentId from the MIME part that is represented by the attachment entry. |
| data | `byte[]` | Carries the content of the MIME element as a byte array. |

### Bound attachment entry

| Property name | Property type | Property description |
|---|---|---|
| contentType | `java.lang.String` | Carries the contentType from the MIME part that is represented by the attachment entry. |
| contentTransferEncoding | `java.lang.String` | Carries the contentTransferEncoding from the MIME part that is represented by the attachment entry. |
| contentId | `java.lang.String` | Carries the contentId from the MIME part that is represented by the attachment entry. |
| messagePart | `java.lang.String` | Contains the name of the message part that carries the data from this attachment. |

### Message body layout

The layout of the data object in the body is defined by the service WSDL. The type of the data object is derived from the message definition in the WSDL. The data object has one property for each part in the message definition. The layout of each message part follows the convention for mapping XML Schema into SDO. See “Web Services code example” on page 1305 for more information.

### Web services fault message

If the message is a fault message, the messageType field in the Info node of the graph is set to "fault", and the message body has the following properties:

| Property name | Property type | Property description |
|---|---|---|
| faultcode | `javax.xml.namespace.QName` | Carries the faultcode value from the SOAP Fault element |

| | | |
|---|---|---|
| faultstring | `java.lang.String` | Carries the faultstring value from the SOAP Fault element |
| faultactor | `java.lang.String` | Carries the faultactor value from the SOAP Fault element |
| detail | `commonj.sdo.DataObject` | Carries the content within the detail child of the SOAP Fault element |

**Note:** The detail element definition uses element and attribute wildcards, so the content of the detail data object contains a Sequence. See “Web Services code example” on page 1305 for more information.

*Mapping XML schema definitions to the SDO type system:*

Each XML schema type is mapped to an SDO type. Use this mapping to help you develop code to navigate the data graphs of the messages that your program mediates.

The version of Service Data Objects (SDO) supported by mediations is Version 1.

XML schemas can be embedded in the WSDL sections that describe the message parts and SOAP headers. However the SOAP header description is more likely to be available as a separate schema, in which case you should load it into the SDO repository where it can be used at run time to process any message with a matching header.

**Schema to Java class mapping**

Each XML schema complex type is mapped to an SDO type. This means that an element with a complex type is represented by an instance of an SDO data object. The type has a property for each element, attribute, or wildcard that is contained in the schema type definition.

The instance contains a value for each property that has been set. If the property is mapped from a schema complex type, the value is another SDO data object. If the property is mapped from a schema simple type, the value is an instance of a Java class, as shown in the following table.

*Table 162. Schema types and corresponding Java classes. The first column of the table lists the schema types. The second column lists the corresponding Java classes. The third column refers you to one of the two notes that is given at the end of the table for your reference.*

| Schema type | Java class | Notes |
|---|---|---|
| anyURI | java.lang.String | |
| base64Binary | byte[] | See Note 2 |
| boolean | java.lang.Boolean/ boolean | See Note 1 |
| byte | java.lang.Byte / byte | See Note 1 |
| date | java.lang.String | |
| dateTime | java.lang.String | |
| decimal | java.math.BigDecimal | |
| double | java.lang.Double / double | See Note 1 |
| duration | java.lang.String | |
| ENTITIES | java.util.List | |
| ENTITY | java.lang.String | |
| float | ava.lang.Float / float | See Note 1 |
| gDay | java.lang.String | |
| gMonth | java.lang.String | |
| gMonthDay | java.lang.String | |

*Table 162. Schema types and corresponding Java classes (continued). The first column of the table lists the schema types. The second column lists the corresponding Java classes. The third column refers you to one of the two notes that is given at the end of the table for your reference.*

| | | |
|---|---|---|
| gYear | java.lang.String | |
| gYearMonth | java.lang.String | |
| hexBinary | byte[] | See Note 2 |
| ID | java.lang.String | |
| IDREF | java.lang.String | |
| IDREFS | java.util.List | |
| int | java.lang.Integer / int | See Note 1 |
| integer | java.math.BigInteger | |
| language | java.lang.String | |
| long | java.lang.Long / long | See Note 1 |
| Name | java.lang.String | |
| NCName | java.lang.String | |
| negativeInteger | java.math.BigInteger | |
| NKTOKENS | java.util.List | |
| NMTOKEN | java.lang.String | |
| nonNegativeInteger | java.math.BigInteger | |
| nonPositiveInteger | java.math.BigInteger | |
| normalisedString | java.lang.String | |
| NOTATION | javax.xml.namespace.QName | |
| positiveInteger | java.math.BigInteger | |
| QName | javax.xml.namespace.QName | |
| short | java.lang.Short / short | See Note 1 |
| string | java.lang.String | |
| time | java.lang.String | |
| token | java.lang.String | |
| unsignedByte | java.lang.Short / short | See Note 1 |
| unsignedInt | java.lang.Long / long | See Note 1 |
| unsignedLong | java.math.BigInteger | |
| unsignedShort | java.lang.Integer / int | See Note 1 |

**Notes:**

1. SDO automatically converts primitives (int, long and so on) into objects, as needed. This means that you can use a mixture of the specialized methods (getInt, setInt, getLong, setLong) as well as the generic get and set methods.
2. As byte arrays are mutable, you can update the value without setting it back onto the data object. However, when this occurs, the data object may not be aware of implicit update. When working with byte array values, always use the setBytes() method to explicitly update the data object.

### Working with global elements and attributes

When a schema is mapped to SDO, a special SDO type - typically called 'DocumentRoot' - is defined. This type is a container for all the global elements and attributes in the schema. Whenever you have to locate an SDO property for a global element or attribute, you should locate the ‘DocumentRoot' type and then locate the appropriate property within it.

The following schema defines the layout of web services messages. By comparing this schema with the information in “Mapping of SDO data graphs for web services messages” on page 1298 you can see the schema to SDO mapping in action.

```
<?xml version="1.0"?>
<xsd:schema
    targetNamespace="http://www.ibm.com/ns/2004/05/webservices/messagemodel"
    xmlns:tns="http://www.ibm.com/ns/2004/05/webservices/messagemodel"
    xmlns:xsd="http://www.w3.org/2001/XMLSchema"

      </xsd:extension>
    </xsd:complexContent>
  </xsd:complexType>

</xsd:schema>
```

*Web Services code example:*

This Web Services Description Language (WSDL) example and code snippets show how to access fields within a Web services message for programming a mediation.

**Web services message definition**

This topic contains an example of a web services message. The example is characterized in WSDL, an XML-based language that is used to describe the services a business offers and how those services might be accessed.

This topic shows how to program mediations to work with different parts of a web services message, which are described with the Service Data Objects (SDO) Version 1 representation in “Mapping of SDO data graphs for web services messages” on page 1298. For each part of the message, there is an XML description of the message, representing its SDO data graph. Each XML description is accompanied by code snippets that illustrate how to work with that part of the message.

**Note:** In the following example, the SOAP header schema is included in the WSDL. Alternatively, it can be included as a separate schema in the SDO repository.

This is a WSDL description of the message that is used as an example for subsequent code snippets:

**companyInfo web service message description**

```
<wsdl:definitions targetNamespace="http://example.companyInfo"
 xmlns:tns="http://example.companyInfo"
 xmlns:wsdl="http://schemas.xmlsoap.org/wsdl/"
 xmlns:wsdlsoap="http://schemas.xmlsoap.org/wsdl/soap/"
 xmlns:wsdlmime="http://schemas.xmlsoap.org/wsdl/mime/"
 xmlns:xsd="http://www.w3.org/2001/XMLSchema">

 <wsdl:types>
  <xsd:schema elementFormDefault="qualified"
   targetNamespace="http://example.header">

   <xsd:element name="sampleHeader">
    <xsd:complexType>
     <xsd:all>
      <xsd:element name="priority" type="xsd:int"/>
     </xsd:all>
    </xsd:complexType>
   </xsd:element>
  </xsd:schema>

  <xsd:schema elementFormDefault="qualified"
   targetNamespace="http://example.companyInfo">

   <xsd:element name="getCompanyInfo">
    <xsd:complexType>
     <xsd:all>
      <xsd:element name="tickerSymbol" type="xsd:string"/>
     </xsd:all>
    </xsd:complexType>
   </xsd:element>

   <xsd:element name="getCompanyInfoResult">
    <xsd:complexType>
     <xsd:all>
      <xsd:element name="result" type="xsd:float"/>
     </xsd:all>
    </xsd:complexType>
   </xsd:element>
  </xsd:schema>

 </wsdl:types>

 <wsdl:message name="getCompanyInfoRequest">
   <wsdl:part name="part1" element="tns:getCompanyInfo"/>
 </wsdl:message>

 <wsdl:message name="getCompanyInfoResponse">
  <wsdl:part name="part1" element="tns:getCompanyInfoResult"/>
  <wsdl:part name="part2" type="xsd:string"/>
  <wsdl:part name="part3" type="xsd:base64Binary"/>
 </wsdl:message>

 <wsdl:portType name="CompanyInfo">
  <wsdl:operation name="GetCompanyInfo">
```

```
   <wsdl:input message="tns:getCompanyInfoRequest"
               name="getCompanyInfoRequest"/>
   <wsdl:output message="tns:getCompanyInfoResponse"
                name="getCompanyInfoResponse"/>
  </wsdl:operation>
 </wsdl:portType>

 <wsdl:binding name="CompanyInfoBinding" type="tns:CompanyInfo">
  <wsdlsoap:binding style="document" transport="http://schemas.xmlsoap.org/soap/http"/>

  <wsdl:operation name="GetCompanyInfo">
   <wsdlsoap:operation soapAction=""/>
   <wsdl:input name="getCompanyInfoRequest">
    <wsdlsoap:body use="literal"/>
   </wsdl:input>
   <wsdl:output name="getCompanyInfoResponse">
    <wsdlsoap:body use="literal"/>
   </wsdl:output>
  </wsdl:operation>
 </wsdl:binding>

 <wsdl:service name="CompanyInfoService">
  <wsdl:port binding="tns:CompanyInfoBinding" name="SOAPPort">
   <wsdlsoap:address location="http://somewhere/services/CompanyInfoService"/>
  </wsdl:port>
 </wsdl:service>

</wsdl:definitions>
```

### Working with the info node

This is an example of a simple SOAP request:

```
<env:Envelope
  xmlns:env='http://schemas.xmlsoap.org/soap/envelope/'
  xmlns:ns1='http://example.companyInfo'>
    <env:Body>
        <ns1:getCompanyInfo>
            <ns1:tickerSymbol>IBM</ns1:tickerSymbol>
        </ns1:getCompanyInfo>
    </env:Body>
</env:Envelope>
```

You can access the properties of the info node (see “Overall layout of a web services message” on page 1298) using code snippets such as this:

```
 // Get the info node (a child of the graph root object)
 DataObject rootNode = graph.getRootObject();
 DataObject infoNode = rootNode.getDataObject("Info");

  // Query the operationName, and messageType.
  String opName = infoNode.getString("operationName");
  String type   = infoNode.getString("messageType");
```

### Working with a header

This is an example of a SOAP request including a header:

```
<env:Envelope
  xmlns:env='http://schemas.xmlsoap.org/soap/envelope/'
  xmlns:ns1='http://example.companyInfo'>
    <env:Header>
        <example:sampleHeader
          env:mustUnderstand='1'
          xmlns:example='http://example.header'>
```

```
            <example:priority>4</example:priority>
        </example:sampleHeader>
    </env:Header>
    <env:Body>
        <ns1:getCompanyInfo>
            <ns1:tickerSymbol>IBM</ns1:tickerSymbol>
        </ns1:getCompanyInfo>
    </env:Body>
</env:Envelope>
```

For a description of the properties of the header entry with a list of headers, see “Header entry” on page 1300. To work with a header entry and its properties, use code such as this:

```
   // Get the info node (a child of the graph root object)
    DataObject rootNode = graph.getRootObject();
    DataObject infoNode = rootNode.getDataObject("Info");

    // Access the list of headers
    List headerEntries = infoNode.getList("headers");

    // Get the first entry from the list
    DataObject headerEntry = (DataObject) headerEntries.get(0);

    // Query the mustUnderstand property of the header entry
    boolean mustUnderstand = headerEntry.getBoolean("mustUnderstand");

    // Get the Sequence that holds the content of the header entry
    Sequence headerContent = headerEntry.getSequence("any");

    // Get the first piece of content from the Sequence
    DataObject header = (DataObject) headerContent.getValue(0);

    // Read the priority from the header
    int priority = header.getInt("priority");

    // Shorthand for the above, using SDO path expressions that start
    // from the info node.
    mustUnderstand = infoNode.getBoolean("headers[1]/mustUnderstand");
    priority       = infoNode.getInt("headers[1]/any[1]/priority");
```

### Working with an attachment

This is an example of a SOAP request including an XML attachment:

```
Content-Type: multipart/related; start="<start>"; boundary="boundary"

--boundary
Content-Type: text/xml
Content-Transfer-Encoding: 7bit
Content-ID: <start>

<env:Envelope
  xmlns:env='http://schemas.xmlsoap.org/soap/envelope/'
  xmlns:ns1='http://example.companyInfo'>
    <env:Body>
        <ns1:getCompanyInfo>
            <ns1:tickerSymbol>IBM</ns1:tickerSymbol>
        </ns1:getCompanyInfo>
    </env:Body>
</env:Envelope>
--boundary
Content-Type: text/xml; charset=UTF-8
Content-Transfer-Encoding: binary
```

```
Content-ID: <myAttachment>

<info>Some attached information</info>
--boundary--
```

For a description of the properties of the attachment entry with byte array, see “Attachment entry” on page 1301. To work with a header entry and its properties, use code such as this:

```
  // Get the info node (a child of the graph root object)
    DataObject rootNode = graph.getRootObject();
    DataObject infoNode = rootNode.getDataObject("Info");

    // Access the list of attachments
    List attachmentEntries = infoNode.getList("attachments");

    // Get the first entry from the list
    DataObject attachmentEntry = (DataObject) attachmentEntries.get(0);

    // Query the contentId property of the header entry
    String contentId = attachmentEntry.getString("contentId");

    // Get the data contained in the attachment
    byte[] data = attachmentEntry.getBytes("data");
```

### Working with the message body

This is an example of a simple SOAP request:

```
<env:Envelope
  xmlns:env='http://schemas.xmlsoap.org/soap/envelope/'
  xmlns:ns1='http://example.companyInfo'>
    <env:Body>
        <ns1:getCompanyInfo>
            <ns1:tickerSymbol>IBM</ns1:tickerSymbol>
        </ns1:getCompanyInfo>
    </env:Body>
</env:Envelope>
```

To see the properties of the body, see “Message body layout” on page 1301. To work with the contents of the body, use code such as this:

```
    // Get the info node (a child of the graph root object)
    DataObject rootNode = graph.getRootObject();
    DataObject infoNode = rootNode.getDataObject("Info");

    // Get hold of the body node
    DataObject bodyNode = infoNode.getDataObject("body");

    // Get hold of the data object for the first part of the body
    DataObject part1Node = bodyNode.getDataObject("part1");

    // Query the tickerSymbol
    String ticker = part1Node.getString("tickerSymbol");

    // Shorthand for the above, using a SDO path expression that
    // starts from the info node.
    ticker = infoNode.getString("body/part1/tickerSymbol");
```

*JMS formats:*

To write code that can access the different JMS message types, you need to know how each message type is mapped to SDO, and how to retrieve the message format string from the message.

### Format types

Each JMS message type is defined by a message format string within the message. You can retrieve the format string by using the code snippet in the example below. The following table shows the mapping of message format strings to Service Data Objects (SDO):

| JMS Message type | Message format string | Mapping to SDO[1] |
|---|---|---|
| JMS Bytes message | `JMS:bytes` | See “JMS Formats - bytes” |
| JMS Text message | `JMS:text` | See “JMS Formats - text” |
| JMS Stream message | `JMS:stream` | See “JMS formats - Stream” on page 1311 |
| JMS Object message | `JMS:object` | See “JMS Formats - object” on page 1311 |
| JMS Map message | `JMS:map` | The retrieval or construction of SDO data graphs for JMS map messages is not supported. |

[1] The version of SDO supported by mediations is Version 1.

This code snippet is an example of how to retrieve the message format string from the message:

```
String format = siMsg.getFormat();
if (format.equals ....
```

*JMS Formats - bytes:*

Your program can retrieve the payload of a JMS bytes message by mapping the body of the message to an SDO data graph representing the message.

### Bytes body

You can retrieve the payload of a JMS bytes message as a Java byte array (`byte[]`). First, you must retrieve a data graph representing the message from the SIMessage instance. As is common to all data graphs representing JMS messages, the root data object of the graph contains a property named "data", and that data object in turn contains a property named "value". In JMS bytes messages, the value property might be accessed as a Java byte array.

You can access the data within the data graph with code such as this:

```
SIMessage siMsg;
String format = siMsg.getFormat();
if (format.equals("JMS:bytes")) {
  DataGraph graph = siMsg.getDataGraph();
  byte[] payload = graph.getRootObject().getBytes("data/value");
}
```

*JMS Formats - text:*

Your program can retrieve the payload of a JMS text message by mapping the body of the message to an SDO data graph representing the message.

### Text body

You can retrieve the payload of a JMS text message as a Java string value (java.lang.String). First, you must retrieve a data graph representing the message from the SIMessage instance. As is common to all data graphs representing JMS messages, the root data object of the graph contains a property named

"data", and that data object in turn contains a property named "value". In JMS text messages the value property may be accessed as a Java string value.

You can access the data within the data graph with code such as this:

```
SIMessage siMsg;
String format = siMsg.getFormat();
if (format.equals("JMS:text")) {
  DataGraph graph = siMsg.getDataGraph();
  String payload = graph.getRootObject().getString("data/value");
}
```

*JMS formats - Stream:*

Your program can retrieve the payload of a JMS stream message by mapping the body of the message to an SDO data graph representing the message.

**Stream body**

You can retrieve the payload of a JMS Stream message as a Java list value (java.util.List). First, you must retrieve a data graph representing the message from the SIMessage instance. As is common to all data graphs representing JMS messages, the root data object of the graph contains a property named "data", and that data object in turn contains a property named "value". For a JMS Stream message the value property might be accessed as a List value. The member functions of the List interface can be used to access the individual objects within the JMS Stream message instance. (Note that the JMS standard places constraints on the kinds of objects that might be placed in a Stream message.)

You can access the data within the data graph with code such as this:

```
}SIMessage siMsg;
String format = siMessage.getFormat();
if (format.equals("JMS:stream")) {
  DataGraph graph = siMsg.getDataGraph();
  List payload = graph.getRootObject().getList("data/value");
  int streamLength = payload.size();
  if (streamLength > 0) {
    Object item1 = payload.get(0);
    // You can also access items directly, for example: (for the_same_ value)
    item1 = graph.getRootObject().get("data/value[1]");
  }
}
```

*JMS Formats - object:*

Your program can retrieve the payload of a JMS object message by mapping the body of the message to an SDO data graph representing the message.

**Object body**

You can retrieve the payload of a JMS object message as a Java byte array (`byte[]`). First, you must retrieve a data graph representing the message from the SIMessage instance. As is common to all data graphs representing JMS messages, the root data object of the graph contains a property named "data", and that data object in turn contains a property named "value". For a JMS object message the value property might be accessed as a Java byte array. The original Object instance that the payload represents might be reconstructed from the byte array.

You can access the data within the data graph with code such as this:

```
SIMessage siMsg;
String format = siMsg.getFormat();
if (format.equals("JMS:object")) {
  DataGraph graph = siMsg.getDataGraph();
  byte[] payload = graph.getRootObject().getBytes("data/value");
  if(payload != null) {
    // Need to deserialize to recover original object
    ObjectInputStream in =
      new ObjectInputStream(new ByteArrayInputStream(payload));
    Object obj = in.readObject();
  }
}
```

# Writing a routing mediation

Use this topic to create a mediation that chooses a particular forward route for a message.

## Before you begin

For an introduction to using mediations with the service integration bus, see Learning about mediations. For details of how to install a mediation into WebSphere Application Server and associate it with a bus destination, see Working with mediations.

This topic assumes that you are familiar with using a Java Platform, Enterprise Edition (Java EE) session bean development environment such as the assembly tools or IBM Rational Application Developer.

## About this task

A routing mediation is a mediation application that contains a routing handler. You associate a routing mediation with a service integration bus destination, and use the mediation to choose a particular route from a range of available routes. For example when you create a new outbound service configuration or modify an existing outbound service configuration you can apply a port selection mediation to choose a particular outbound port from the range of ports that are available to the outbound service.

To create a routing mediation, use a Java Platform, Enterprise Edition (Java EE) session bean development environment to complete the following steps:

## Procedure

1. Create an empty mediation handler project. This creates the project, and creates the handler class that implements the handler interface. For detailed instructions on how to do this, see Writing the mediation handler.
2. Use the mediation pane on the EJB descriptor to define the handler class as a mediation handler.

   **Note:** When you do this, you specify a name by which the mediation handler list is known. Make a note of this name, for later reference when you create the mediation in the bus.
3. Add the routing function to the handler. Before you begin, review Adding mediation function to handler code, in particular its subtopic Working with message context. Add import statements to your handler class, and modify the handle method by adding your routing code. Specify the routing destination by adding that destination to the front of the forward routing path list. The forward routing path list is available from the message context. For example:

```
import javax.xml.rpc.handler.MessageContext;
import com.ibm.websphere.sib.mediation.handler.MediationHandler;
import com.ibm.websphere.sib.mediation.handler.MessageContextException;
import com.ibm.websphere.sib.mediation.messagecontext.SIMessageContext;
import com.ibm.websphere.sib.SIMessage;
import com.ibm.websphere.sib.SIDestinationAddress;
import com.ibm.websphere.sib.SIDestinationAddressFactory;
import java.util.List;
```

```
public class RouteMediationHandler implements MediationHandler {

 public boolean handle(MessageContext ctx) throws MessageContextException {
  SIMessageContext siCtx = (SIMessageContext) ctx;
  SIMessage msg = siCtx.getSIMessage();
  List frp = msg.getForwardRoutingPath();
  try {
   SIDestinationAddress destination =
    SIDestinationAddressFactory
     .getInstance()
     .createSIDestinationAddress(
     "RoutingDestination", //this is the name of the target destination
     false);
   frp.add(0, destination);
  } catch (Exception e) {
   return false;
  }
  msg.setForwardRoutingPath(frp);
  return true;
 }

}
```

For more information about the service integration technologies classes, including the mediation handler and message context classes, see the Generated API documentation - Application programming interfaces .

4. Export the routing mediation enterprise application.

### What to do next

You are now ready to install your mediation into WebSphere Application Server and associate it with a bus destination, as described in Working with mediations.

## Writing a mediation that maps between attachment encoding styles

Use this topic to create a mediation that maps from SOAP Messages with Attachments encoding style to WS-I Attachments Profile Version 1.0 encoding style.

### Before you begin

For an introduction to using mediations with the service integration bus, see Learning about mediations. For details of how to install a mediation into WebSphere Application Server and associate it with a bus destination, see Working with mediations.

This topic assumes that you are familiar with using a Java Platform, Enterprise Edition (Java EE) session bean development environment such as the assembly tools or IBM Rational Application Developer.

The example mediation given in this topic is based upon the WSDL examples that are given in Supporting bound attachments: WSDL examples

### About this task

You can use a mediation to map from a SOAP Messages with Attachments encoding of a message to WS-I Attachments Profile Version 1.0 encoding. The WSDL definition is the same in both cases, so if you create a mediation that rewrites the Content ID values to match the Version 1.0 conventions then the message is encoded by service integration technologies according to Version 1.0 rules.

To create a mapping mediation, use a Java Platform, Enterprise Edition (Java EE) session bean development environment to complete the following steps:

### Procedure

1. Create an empty mediation handler project. This creates the project, and creates the handler class that implements the handler interface. For detailed instructions on how to do this, see Writing the mediation handler.
2. Use the mediation pane on the EJB descriptor to define the handler class as a mediation handler.

   **Note:** When you do this, you specify a name by which the mediation handler list is known. Make a note of this name, for later reference when you create the mediation in the bus.
3. Add the mapping function to the handler. Before you begin, review Adding mediation function to handler code. Here is an example of mediation handler code that rewrites the Content ID values to match the Version 1.0 conventions:

```
int uuidBase = 0;
DataObject root = SIMessage.getDataGraph().getRootObject();
List attachments = root.getList("info/attachments");
Iterator entries = attachments.iterator();
while(entries.hasNext()) {
  DataObject entry = (DataObject) entries.next();
  if(entry.getType().equals("BoundMIMEAttachmentEntryType")) {
    String newContentId = entry.getString("messagePart") + "=" +
                          Integer.toString(uuidBase++) +
                          "@some.domain";
  }
}
```

   **Note:** For messages that use a SOAP with attachments reference (swaref) or some other URI mechanism to refer to the attachments, the URI values might also have to be updated to match the new Content ID values. However such mechanisms are usually used to refer to unbound attachments.

   For more information about the service integration technologies classes, including the mediation handler classes, see the Generated API documentation - Application programming interfaces .
4. Export the mapping mediation enterprise application.

### What to do next

You are now ready to install your mediation into WebSphere Application Server and associate it with a bus destination, as described in Working with mediations.

## Using durable subscriptions

You use *durable subscriptions* for publish/subscribe messaging. A durable subscription can be used to preserve messages published on a topic while the subscriber is not active.

### About this task

If there is no active subscriber for a durable subscription, JMS retains the subscription messages until they are received by the subscriber, or until they expire, or until the durable subscription is deleted. This enables subscriber applications to operate disconnected from the JMS provider for periods of time, and then reconnect to the provider and process messages that were published during their absence.

Each JMS durable subscription is identified by a subscription name (*subName*), which is defined when the durable subscription is created. A JMS connection also has an associated client identifier (*clientID*), which is used to associate a connection and its objects with the list of messages (on the durable subscription) that is maintained by the JMS provider for the client. The subName assigned to a durable subscription must be unique within a given client ID.

If an application needs to receive messages published on a topic while the subscriber is inactive, it uses a *durable subscriber*.

In normal operation there can be at most one active (connected) subscriber for a durable subscription at a time. However, when running inside an application server it is possible to clone the application server for failover and load-balancing purposes. In this case, a cloned durable subscription can have multiple simultaneous consumers.

For information about durable subscriptions, see the JMS 1.1 Specification (for example, section 9.3.3 “Using Durable Subscriptions”).

The following operations for durable subscriptions are in addition to the usual JMS operations, such as to first look up a connection factory and a JMS destination, and to create a connection and session.

The following are the main operations for using durable subscriptions:

- Creating a new durable subscription
- Reconnecting to an existing durable subscription
- Unsubscribing (deleting) a durable subscription

## Procedure

- Define the Durable Subscription Home This property must be set on the JMS connection factory if durable subscriptions are to be created using connections created from this connection factory. The value is the name of the messaging engine where all durable subscriptions accessed through this connection are managed.

  You can also set the Durable Subscription Home on the JMS topic destination, which enables a single connection to access durable subscriptions on more than one messaging engine.

  To be able to create durable subscriptions, the property on the connection factory must not be null (the default). Setting a value of null or empty string on the property of a destination indicates that the value specified on the connection factory should be inherited.
- Creating a new durable subscription A durable TopicSubscriber can be created by a Session or by a TopicSession.

  Having performed the normal setup, an application can create a durable subscriber to a destination. To do this, the client program creates a durable TopicSubscriber, by using session.createDurableSubscriber. The name *subName* is used as an identifier of the durable subscription.

  ```
  session.createDurableSubscriber( Topic topic,
          java.lang.String subName,
          java.lang.String messageSelector,
          boolean noLocal);
  ```

  Alternatively, you can use the two-argument form of this operation, which takes only a topic and name (*subName*) as parameters. This alternative form invokes the four-argument operation with null as the messageSelector and false as the noLocal parameters.

  ```
  session.createDurableSubscriber( Topic topic, java.lang.String subName);
  ```

  A JMS durable subscription is created with a unique identifier of the form *clientID*+"##"+*subName*. The characters ## should not be used in the clientID or subName if the JMS connection is to use a durable subscription.

  Handling exceptions. The following JMS exceptions can be thrown for the reasons listed in the exception messages:

  – InvalidDestination - The name of this durable subscription (*clientID*+"##"+*subName*) clashes with an existing destination.
  – IllegalState - The method was invoked on a closed connection.
  – IllegalState - This destination is not accepting consumers. This probably means that there is already an active subscriber for this durable subscription.
  – InvalidDestination - The mediation named in the parameters cannot be found.
  – InvalidDestination - The destination cannot be found.

  - JMSSecurity - The user does not have authorization to perform this operation.
  - JMSException - Errors occurred in the MsgStore, Comms or Core layers.
- Reconnecting to an existing durable subscription To reconnect to a topic that has an existing durable subscription, the subscriber application calls `session.CreateDurableSubscriber` again, using the same parameters that it used to originally create the durable subscription. However, consider the following important restrictions:
  - The subscriber must be attached to the same connection.
  - The destination and subscription name must be the same as in the original method call.
  - If a message selector was specified, it must be the same as in the original method call.

  By calling createDurableSubscriber again, the subscriber application reconnects to the topic, and receives any messages that arrived while the subscriber was disconnected.
- Unsubscribing (deleting) a durable subscription To unsubscribe (delete) a durable subscription to a topic, the subscriber application calls `session.unsubscribe(java.lang.String` *`name`*`)`.

  Do not call the unsubscribe method to delete a durable subscription if there is a TopicConsumer currently consuming messages from the topic.

## Sending web service messages directly over the bus from a JAX-RPC client

Use this task to send web service messages over a bus by retargeting the JAX-RPC client.

### About this task

Java API for XML-based remote procedure calls (JAX-RPC) client applications send and receive web service request and response messages. JAX-RPC client applications that use the IBM JAX-RPC run-time environment can do this in a number of different ways, depending on the bindings in the WSDL document that they are developed against, and the configuration data that is used at run time.

For an introduction to basic JAX-RPC programming concepts, including the JAX-RPC client and server programming models, see Getting Started with JAX-RPC.

If you want to use a JAX-RPC client to send messages over the service integration bus, you have two choices:

- Use a SOAP binding (SOAP over HTTP or SOAP over JMS), and pass messages indirectly through an endpoint listener to an inbound service. You would do this if you had SOAP-specific JAX-RPC handlers that must run in the client application context.
- Pass messages directly into the service integration bus at a destination by “retargeting” the JAX-RPC client application as described in this topic.

  **Note:** There are currently limitations regarding the Java types used by services that are retargeted through a JAX-RPC client application.

Retargeting involves setting the following two values into the client application deployment descriptor, or specifying them dynamically at run time from within the client application:

- The *binding namespace* is set to indicate that the client uses the messaging bus directly.
- The *endpoint address* is set to include the particular destination and (optionally) the format of messages that the client uses.

The destination also needs to be configured so that it knows the port type of messages that the JAX-RPC client is using. There are two ways to achieve this:

- Create an outbound service. An outbound service represents an externally-provided web service. In this case, requests from the JAX-RPC client pass through the service destination and are then sent on to the service provider defined by the outbound service configuration.
- Create an inbound service. An inbound service represents a service provided somewhere within or beyond the messaging bus. You can create an inbound service on any existing destination. The creation of an inbound service associates a WSDL port type with the destination. When retargeting to a destination with an inbound service, the client application needs to specify both the destination name and inbound service name, because it is possible to configure more than one inbound service against a single destination. In this case, requests from the JAX-RPC client pass through the destination and then onwards through the service integration bus depending on routing that is done at the initial destination.

To have web service messages sent directly to a destination using a JAX-RPC client, complete the following steps:

### Procedure

1. Create the JAX-RPC client application.
2. Create the outbound service or inbound service with which you want the JAX-RPC client application to exchange messages.
3. Use the administrative console to access the port information for your JAX-RPC client application, as described in “Configuring web services client bindings” on page 1611 and Web services client port information.
4. Override the default SOAP binding for your JAX-RPC client application. Change the binding namespace to `http://www.ibm.com/ns/2004/02/wsdl/mp/sib`
5. Override the endpoint that your JAX-RPC client application uses to send web service requests. The new endpoint should use the sib: URL syntax and include either the outbound service destination name, or both the inbound service name and its corresponding destination name.

### What to do next

After you change the *binding namespace*, any JAX-RPC handler lists that were configured for the retargeted port are ignored. For clients that are developed against WSDL with a SOAP binding, retargeting directly to the bus causes the handlers to be ignored. However if the client is developed against the non-bound WSDL for the service, retargeting to the bus is not considered to be changing the binding namespace, and so the handler information is retained. In this case the JAX-RPC handlers are called with the SDOMessageContext subclass.

Associated reference information:

- “sib: URL syntax”

## sib: URL syntax

The `sib:` URL has the following syntax:

`sib:/[destination|path]?`*`property_1=value_1&property_2=value_2&...`*

where:

- Square brackets (“[ ]”) indicate that a parameter is optional.
- Transport type is `sib:`, followed by either `/destination` to specify destination type or `/path` to specify a forward routing path, followed by a “query string” that contains one or more properties. The permitted properties are described in the subsequent sections of this topic.

### Required properties

The following properties are required. They are used to specify the destination for the request.

**Note:** All destination names must be fully-qualified. That is, they must include the name of the service integration bus as well as the destination name itself. Use the syntax *bus*:*destination*. If a bus or destination name contains a colon or comma, wrap the name in double quotation marks (“”). If it contains a double quotation mark, repeat the quotation mark.

**destinationName**
The destination name.

**path** The forward routing path, in the form of a sequence of destination names separated by commas.

**replyDestinationName**
The name of the destination to be used for the reply.

**inboundService**
The name of the inbound service that identifies the specific attachment that the requester application uses. You can omit this value if the destination is a service destination with an associated outbound service configuration, because in that case the requester is attaching to the outbound service through the service destination.

**timeout**
The time the requester waits for a response. The default value is 60 seconds. A zero value indicates an unlimited wait.

## Service integration technologies-related properties

The following properties are optional. If you do not specify a value for a property, then the default value is used. For more information regarding the permitted values for these properties, see the generated API information for the SIMessage interface.

**reliability**
The reliability of the request message.

**timeToLive**
The amount of time (in milliseconds) before the request times out. A zero value indicates that the request never times out.

**Note:** The **timeout** property (see the required properties) is the time delay after which the requester application blocks the application thread that is waiting for a response to a request and response operation. The **time to live** and **replyTimeToLive** optional properties indicate how long the request and reply messages should be processed by the messaging engines. This does not include the processing time at the service implementation. You would therefore usually set the timeout to be the sum of the request and response times to live, plus some amount for the service processing time.

**priority**
The priority of the request message.

**user**
The user ID required to access the request destination.

**password**
The password required to access the request destination.

**replyReliability**
The reliability of the reply message.

**replyTimeToLive**
The amount of time (in milliseconds) before the reply times out. A zero value indicates that the reply never times out.

**replyPriority**
The priority of the reply message.

## Other properties

You can also include user-defined properties in the URL. These properties must be named with a `user.` prefix. For example:

```
sib:/destination?destinationName=myBus:myDestination & reliability=assured & user.customData=XYZ
```

After the request is sent, the URL itself is available within the message properties, named `inbound.url`.

# Chapter 29. Developing Session Initiation Protocol (SIP) applications

This page provides a starting point for finding information about SIP applications, which are Java programs that use at least one Session Initiation Protocol (SIP) servlet written to the JSR 116 specification.

SIP is used to establish, modify, and terminate multimedia IP sessions including IP telephony, presence, and instant messaging.

## Developing SIP applications

A SIP application is a set of SIP servlets packaged in a SIP application archive file (SAR).

### About this task

A SIP servlet is an application component managed by the SIP container that performs SIP signaling. The programming and deployment models are analogous to web servlets and therefore will be mapped to the WebSphere administrative model accordingly. It is possible to include web servlets in a SAR file (along with the required web.xml deployment descriptor) to create what is known as a converged application. See JSR 116 for details on SIP applications, servlets, converged applications, and status codes.

## Developing SIP applications that support PRACK

A SIP response to an INVITE request can be final or provisional. Final responses are always sent reliably, but provisional responses typically are not. For cases where you need to send a provisional response reliably, you can use the PRACK (Provisional response acknowledgement) method.

### Before you begin

For you to be able to develop applications that support PRACK, the following criteria must be met:

- The client that sends the INVITE request must put a 100rel tag in the Supported or the Require header to indicate that the client supports PRACK.
- The SIP servlet must respond by invoking the sendReliably() method instead of the send() method to send the response.

### About this task

PRACK is described in the following standards:

- RFC 3262 (“Reliability of Provisional Responses in the Session Initiation Protocol (SIP)”), which extends RFC 3261 (“SIP: Session Initiation Protocol”), adding PRACK and the option tag 100rel.
- Section 6.7.1 (“Reliable Provisional Responses”) of JSR 116 (“SIP Servlet API Version 1.0”).

### Procedure

- For an application acting as a proxy, do this:
  - Make your application generate and send a reliable provisional response for any INVITE request that has no tag in the To field.
- For an application acting as a user agent client (UAC), do this:
  - Make your application add the 100rel tag to outgoing INVITE requests. The option tag must appear in either the Supported header or the Require header.
  - Within your application's doProvisionalResponse(...) method, prepare the application to create and send PRACK requests for incoming reliable provisional responses. The application must create the PRACK request on the response's dialog through a SipSession.createRequest(...) method, and it must set the RAck header according to RFC 3262 Section 7.2 (“RAck”).

© IBM Corporation 2009

  - The application that acts as an UAC will not receive doPrack( ) methods. The UAC sends INVITE and receives Reliable responses. When the UAC receives the Reliable response, it sends PRACK a request to the UAS and receives a 200 OK on the PRACK so it should next implement doResponse( ) in order to receive it.
- For an application acting as a user agent server (UAS), do this:
  - If an incoming INVITE request requires the 100rel tag, trying to send a 101-199 response unreliably by using the send() method causes an Exception.
  - Make the application declare a SipErrorListener to receive noPrackReceived() events when a reliable provisional response is not acknowledged within 64*T1 seconds, where T1 is a SIP timer. Within the noPrackReceived() event processing, the application should generate and send a 5*xx* error response for the associated INVITE request per JSR 116 Section 6.7.1.
  - Make the application have at most one outstanding, unacknowledged reliable provisional response. Trying to send another one before the first's acknowledgement results in an Exception.
  - Make sure that the application enforces the RFC 3262 offer/answer semantics surrounding PRACK requests containing session descriptions. Specifically, a servlet must not send a 2*xx* final response if any unacknowledged provisional responses contained a session description.

# Setting up SIP application composition

The JSR 116 standard for SIP applications states in section 2.4 that multiple applications may be invoked for the same SIP request. The process of setting up applications to comply with this standard is called application composition.

## About this task

Application composition requires that implementations use a cascaded services model. The cascaded services model requires that service applications triggered on the same host are triggered in sequence, as if the triggering occurred on different hosts. Therefore responses flow upstream and hit applications in the reverse order of the corresponding requests.

The JSR 116 standard does not specify how to implement application composition, thus there are many ways to comply with this standard. For WebSphere Application Server, composition of the application depends on the deployed application order, and on the order of mapping rules within the deployment descriptor of each application.

- For an initial incoming request, the SIP container tries each potential rule in order. When the container finds the $n^{th}$ match, the container invokes the corresponding servlet.
- If the servlet must proxy the request, the container scans the rules again to search for additional matches. When the container finds the $(n+1)^{th}$ match, the container invokes the corresponding servlet.
- Any servlet in the same application as the previously invoked servlet is excluded from the matching process. No servlet can be invoked twice for the same SIP request.

You can specify load on start-up priority. The `<load-on-startup>` in the `sip.xml` defines the order in which servlets are initialized on startup. If this value is lower than zero, the servlets are initialized when the first request is matched to them according to matching rule and composition order. Zero is a legitimate weight for startup initialization order. If this tag does not exist or if it contains a negative value, the servlet does not initialize at startup.

You should also add `<load-on-startup>` to the same tag in the `web.xml` if you are changing it manually. It is the WebContainer that loads servlets (and siplets), and it looks only at the `web.xml`. When deploying a SAR, only the `sip.xml` needs to be changed. The `web.xml` is automatically constructed correctly after deployment.

The load-on-startup tag embedded in the SIP deployment descriptor tag for a servlet dictates the order that the application is loaded on start up of the server. It does not dictate the order that an application gets called when the application is a member of an application composition chain that matches rules to process a new message coming in.

The starting weight for applications and their modules is specified in the `deployment.xml` file. The order in which modules pickup requests on composition is evaluated by applications weight first and then modules weight. The following steps can be completed in any order to specify applications weight or modules weight from the administrative console.

## Procedure

1. To specify the applications (EARs) weight, expand **Enterprise Applications** > ***applicationName*** > **Startup Behavior** and set the startup order.
2. To specify the modules (WARs) weight, expand **Enterprise Applications** > ***applicationName*** > **Manage Modules** and set the starting weight.
3. Restart the changed applications.

## Example

### Specifying load-on-startup priority example:

sip.xml

```
<?xml version="1.0" encoding="UTF-8"?>
<!DOCTYPE sip-app
PUBLIC "-//Java Community Process//DTD SIP Application 1.0//EN"
"http://www.jcp.org/dtd/sip-app_1_0.dtd">
<sip-app>
 <display-name>SIPSampleProxy</display-name>

 <servlet>
  <servlet-name>SIPSampleProxy</servlet-name>
  <servlet-class>sipes.test.container.proxy.SIPSampleProxy</servlet-class>
  <load-on-startup>1</load-on-startup>
 </servlet>

 <servlet-mapping>
  <servlet-name>SIPSampleProxy</servlet-name>
  <pattern>
   <equal>
    <var>request.uri.user</var>
    <value>SIPSampleProxy</value>
   </equal>
  </pattern>
 </servlet-mapping>

 <proxy-config>
  <sequential-search-timeout>1000</sequential-search-timeout>
 </proxy-config>
 <session-config>
  <session-timeout>12</session-timeout>
 </session-config>
</sip-app>
```

web.xml

```
<?xml version="1.0" encoding="UTF-8"?>
<!DOCTYPE web-app PUBLIC "-//Sun Microsystems, Inc.//DTD Web Application 2.3//EN" "http://java.sun.com/dtd/web-app_2_3.dtd">
<web-app id="WebApp">
 <display-name>SIPSampleProxy</display-name>
 <servlet>
  <servlet-name>SIPSampleProxy</servlet-name>
  <display-name>SIPSampleProxy</display-name>
  <servlet-class>sipes.test.container.proxy.SIPSampleProxy</servlet-class>
 </servlet>
 <servlet-mapping>
  <servlet-name>SIPSampleProxy</servlet-name>
  <url-pattern>/SIPSampleProxy</url-pattern>
 </servlet-mapping>
 <welcome-file-list>
  <welcome-file>index.html</welcome-file>
  <welcome-file>index.htm</welcome-file>
  <welcome-file>index.jsp</welcome-file>
  <welcome-file>default.html</welcome-file>
```

```
  <welcome-file>default.htm</welcome-file>
  <welcome-file>default.jsp</welcome-file>
 </welcome-file-list>
</web-app>
```

**Specifying starting weight example:**

The following example is for a stand-alone server.

deployment.xml

```
<?xml version="1.0" encoding="UTF-8" ?>
- <appdeployment:Deployment xmi:version="2.0" xmlns:xmi="http://www.omg.org/XMI"
xmlns:appdeployment="http://www.ibm.com/websphere/appserver/schemas/5.0/appdeployment.xmi"
xmi:id="Deployment_1137951186883">
- <deployedObject xmi:type="appdeployment:ApplicationDeployment" xmi:id="ApplicationDeployment_1137951186883"
deploymentId="0" startingWeight="1" binariesURL="$(APP_INSTALL_ROOT)/OrangeNode08Cell/SipContainerTestSuite.ear"
useMetadataFromBinaries="false" enableDistribution="true" createMBeansForResources="true" reloadEnabled="false"
appContextIDForSecurity="href:OrangeNode08Cell/SipContainerTestSuite"
filePermission=".*\.dll=755#.*\.so=755#.*\.a=755#.*\.sl=755" allowDispatchRemoteInclude="false"
allowServiceRemoteInclude="false">
  <targetMappings xmi:id="DeploymentTargetMapping_1137951186883" enable="true" target="ServerTarget_1137951186883" />
  <classloader xmi:id="Classloader_1137951186883" mode="PARENT_FIRST" />
- <modules xmi:type="appdeployment:WebModuleDeployment" xmi:id="WebModuleDeployment_1137951186883"
deploymentId="1" startingWeight="10000" uri="sipunit.war">
  <targetMappings xmi:id="DeploymentTargetMapping_1137951186884" target="ServerTarget_1137951186883" />
  <classloader xmi:id="Classloader_1137951186884" /> </modules>
  <properties xmi:id="Property_1137951186883" name="validateinstall" value="warn" /> </deployedObject>
  <deploymentTargets xmi:type="appdeployment:ServerTarget" xmi:id="ServerTarget_1137951186883"
name="server1" nodeName="OrangeNode10" /> </appdeployment:Deployment>
```

# SIP servlets

This topic describes SIP servlets.

The SIP Servlet 1.0 specification (JSR 116) is standardized through Java Specification Request (JSR) 116. The idea behind the specification is to provide a Java application programming interface (API) similar to HTTP servlets, which provides an easy-to-use SIP programming model. Like the popular HTTP servlet programming model, some flexibility is limited to optimize ease-of-use and time-to-value.

However, the SIP Servlet API is different in many ways from HTTP servlets because the protocol is so different. While SIP is a request-response protocol, there is not necessarily only one response to every one request. This complexity and a need for a high performing solution meant that it was easier to make the SIP servlets natively asynchronous. Also, unlike HTTP servlets, the programming model for SIP servlets sought to make client requests easy to create alongside the other logic being written because many applications act as a client or proxy to other servers or proxies.

## SipServlet requests

Like HTTP servlets, each SIP servlet extends a base javax.servlet.sip.SipServlet class. All messages come in through the service method, which you can extend. However, because there is not a one-to-one mapping of requests to responses in SIP, the suggested practice is to extend the doRequest or doResponse methods instead. When extending the doRequest or doResponse methods, it is important to call the extended method for the processing to complete.

Each request method, which the specification must support, has a doxxx method just like HTTP. In HTTP, methods such as doGet and doPost exist for GET and POST requests. In SIP, doInvite, doAck, doOptions, doBye, doCancel, doRegister, doSubscribe, doNotify, doMessage, doInfo, and doPrack methods exist for each SIP request method.

Unlike an HTTP servlet, SIP servlets have methods for each of the response types that are supported. So, SIP servlets include the doProvisionalResponse, doSuccessResponse, doRedirectResponse, and doErrorResponse responses. Specifically, the provisional responses (1xx responses) are used to indicate status, the success responses (2xx responses) are used to indicate a successful completion of the transaction, the redirect responses (3xx responses) are used to redirect the client to a moved resource or entity, and the error responses (4xx, 5xx, and 6xx responses) are used to indicate a failure or a specific

error condition. These types of response messages are similar to HTTP, but because the SIP Servlet programming model includes a client programming model, it is necessary to have responses handled programmatically as well.

## Clarifications of JSR 116

JSR 289 has made some clarifications to JSR 116, as follows:

- JSR 289 Section 4.1.3: Contact Header Field
- JSR 289 Section 5.2: Implicit Transaction State
- JSR 289 Section 5.8: Accessibility of SIP Servlet Messages

## SIP SipServletRequest and SipServletResponse classes

The SipServletRequest and SipServletResponse classes are similar to the HttpServletRequest and HttpServletResponse classes.

### SipServletRequest and SipServletResponse classes

Each class gives you the capability to access the headers in the SIP message and manipulate them. Because of the asynchronous nature of the requests and responses, this class is also the place to create new responses for the requests. When you extend the doInvite method, only the SipServletRequest class is passed to the method. To send a response to the client, you must call the createResponse method on the Request object to create a response. For example:

```
protected void doInvite(SipServletRequest req) throws
 javax.servlet.ServletException, java.io.IOException {

 //send back a provisional Trying response
 SipServletResponse resp = req.createResponse(100);
resp.send();
```

Because of their asynchronous nature, SIP servlets can seem complicated. However, something as simple as the previous code sample sends a response to a client.

Here is a more complex example of a SIP servlet. With the following method included in a SIP servlet, the servlet blocks all of the calls that do not come from the example.com domain.

```
protected void doInvite(SipServletRequest req) throws
 javax.servlet.ServletException, java.io.IOException {

//check to make sure that the URI is a SIP URI
      if (req.getFrom().getURI().isSipURI()){
                  SipURI uri = (SipURI)req.getFrom.getURI();
                  if (!uri.getHost().equals("example.com")) {
                     //send forbidden response for calls outside domain
                     req.createResponse(SipServletResponse.SC_FORBIDDEN).send();
                     return;
                  }
               }
               //proxy all other requests on to their original destination
               req.getProxy().proxyTo(req.getRequestURI);
        }
```

## SIP SipSession and SipApplicationSession classes

Possibly the most complex portions of the SIP Servlet 1.0 specification are the SipSession and SipApplicationSession classes.

### SIP SipSession and SipApplicationSession classes

Both of these classes have some useful purposes and can act as the primary place to store data in applications that are designed for distributed or highly available environments.

The SipSession class is the best representative of a specific point-to-point communication between two entities and is the closest to the HttpSession object. Because historically no proxying or forking existed for the HTTP request in HTTP servlets, the need for something higher than a single point-to-point session did not exist. However, even HTTP users can see the growing need for this type of function since portlets began essentially forking HTTP requests. The SIP users expect the proxying and forking activities that require multiple layers of SIP session management. The SipSession class is the lowest point-to-point layer.

The SipApplicationSession class represents the higher layer of SIP session management. One SipApplicationSession class can own one or more SipSession objects. However, each SipSession class can be related to one SipSession object only. The SipApplicationSession class also supports the attachment of any number of other protocol sessions. Currently, only HTTP sessions are supported by any implementations. The SipApplicationSession class has a getSessions method, which takes the requested protocol type as an argument.

You might find it useful for many applications to combine HTTP and SIP. For example, you might use this approach to tie together HTTP and SIP sessions to monitor a phone call or to start a phone call through a rich HTTP graphical user interface.

## Example: SIP servlet simple proxy

This is a servlet example of a simple proxy.

### Simple proxy

```
import java.io.IOException;

import javax.servlet.Servlet;
import javax.servlet.ServletException;
import javax.servlet.sip.Proxy;
import javax.servlet.sip.SipFactory;
import javax.servlet.sip.SipServlet;
import javax.servlet.sip.SipServletRequest;
import javax.servlet.sip.SipServletResponse;
import javax.servlet.sip.SipSession;
import javax.servlet.sip.SipURI;
import javax.servlet.sip.URI;

public class SimpleProxy extends SipServlet implements Servlet {

 final static  private String  SHUTDOWN_KEY = new String("shutdown");
 final static  private String  STATE_KEY = new String("state");
 final static  private int   INVITE_RECEIVED = 1;

 /* (non-Java-doc)
  * @see javax.servlet.sip.SipServlet#SipServlet()
  */
 public SimpleProxy() {
  super();
 }

 /* (non-Javadoc)
  * @see javax.servlet.sip.SipServlet#doInvite(javax.servlet.sip.SipServletRequest)
  */
 protected void doInvite(SipServletRequest request) throws ServletException,
   IOException {

  //log("SimpleProxy: doInvite: TOP");

  try {
   if (request.isInitial() == true)
   {
    // This should cause the sip session to be created. This sample only uses the session on receiving
    // a BYE but the Tivoli performance viewer can be used to track the creation of calls by viewing the
```

```
   // active session count.
   Integer state = new Integer(INVITE_RECEIVED);
   SipSession session = request.getSession();
   session.setAttribute(STATE_KEY, state);
            log("SimpleProxy: doInvite: setting attribute");

   Proxy proxy = request.getProxy();

   SipFactory sipFactory = (SipFactory) getServletContext().getAttribute(SIP_FACTORY);
         if (sipFactory == null) {
             throw new ServletException("No SipFactory in context");
         }

         String callingNumber = request.getTo().toString();
         if (callingNumber != null)
         {
             String destStr = format_lookup(callingNumber);
             URI dest = sipFactory.createURI(destStr);

             //log("SimpleProxy: doInvite: Proxying to dest URI = " + dest.toString());

          if (((SipURI)request.getRequestURI()).getTransportParam() != null)
           ((SipURI)dest).setTransportParam(((SipURI)request.getRequestURI()).getTransportParam());

          proxy.setRecordRoute(true);
    proxy.proxyTo(dest);
         }
   else
   {
             //log("SimpleProxy: doInvite: Request is invalid. Did not contain a To: field.");
    SipServletResponse sipresponse = request.createResponse(400);
    sipresponse.send();
   }
  }
  else
  {
         //log("SimpleProxy: doInvite: target refresh, let container handle invite");
   super.doInvite(request);
  }
 }
 catch (Exception e){
  e.printStackTrace();
 }
}

/* (non-Javadoc)
 * @see javax.servlet.sip.SipServlet#doResponse(javax.servlet.sip.SipServletResponse)
 */
protected void doResponse(SipServletResponse response) throws ServletException,
  IOException {
  super.doResponse(response);

  // Example of using the session object to store session state.
 SipSession session = response.getSession();
 if (session.getAttribute(SHUTDOWN_KEY) != null)
 {
  //log("SimpleProxy: doResponse: invalidating session");
  session.invalidate();
 }
}

/* (non-Javadoc)
 * @see javax.servlet.sip.SipServlet#doBye(javax.servlet.sip.SipServletRequest)
 */
protected void doBye(SipServletRequest request) throws ServletException,
  IOException {
```

```
  SipSession session = request.getSession();
  session.setAttribute(SHUTDOWN_KEY, new Boolean(true));

        //log("SimpleProxy: doBye: invalidate session when responses is received.");
  super.doBye(request);
 }

 protected String format_lookup(String toFormat){
  int start_index = toFormat.indexOf('<') + 1;
  int end_index = toFormat.indexOf('>');

  if(start_index == 0){
   //don't worry about it
  }
  if(end_index == -1){
   end_index = toFormat.length();
  }

  return toFormat.substring(start_index, end_index);
 }
}
```

## Example: SIP servlet SendOnServlet class

The SendOnServlet class is a simple SIP servlet that would perform the basic function of being called on each INVITE and sending the request on from there.

### SendOnServlet class

Function could easily be inserted to log this invite request or reject the INVITE based on some specific criteria.

```
package com.example;
import java.io.IOException;
import javax.servlet.sip.*;
import java.servlet.ServletException;
public class SendOnServlet extends SipServlet {
  public void doInvite(SipServletRequest req)
       throws ServletException, java.io.IOException {
     //send on the request
     req.getProxy().proxyTo(req.getRequestURI);
  }
}
```

The doInvite method could be altered to do something such as reject the invite for some specific criteria simply. In the example doInvite method below, all requests from domains outside of example.com will be rejected with a Forbidden response.

```
   public void doInvite(SipServletRequest req)
throws ServletException, java.io.IOException {
if (req.getFrom().getURI().isSipURI()){
    SipURI uri = (SipURI)req.getFrom.getURI();
    if (!uri.getHost().equals("example.com")) {
  //send forbidden response for calls outside domain
req.createResponse(SipServletResponse.SC_FORBIDDEN, "Calls outside example.com not accepted").send();
return;
    }
 }
 //proxy all other requests on to their original destination
 req.getProxy().proxyTo(req.getRequestURI());
   }

SendOnServlet deployment descriptor:
<sip-app>
    <display-name>Send-on Servlet</display-name>
    <servlet>
```

```
        <servlet-name>SendOnServlet</servlet-name>
        <servlet-class>com.example.SendOnServlet</servlet-class>
    </servlet>

    <servlet-mapping>
        <servlet-name>SendOnServlet</servlet-name>
        <pattern>
              <equal>
                <var>request.method</var>
                <value>INVITE</value>
              </equal>
        </pattern>
    </servlet-mapping>
</sip-app>
```

## Example: SIP servlet Proxy servlet class

### Proxy servlet class

After the initial INVITE, this application will be called on every subsequent SIP message. For each Request and Response, this class will simply print out the action and who it is to or from.

```
package com.example;
import java.io.IOException;
import javax.servlet.sip.*;
import java.servlet.ServletException;
public class ProxyServlet extends SipServlet {
  public void doInvite(SipServletRequest req)
       throws ServletException, java.io.IOException {
     //get the Proxy
     Proxy p=req.getProxy();
     //turn on supervised mode so that all events come through us
     //The default on this is true but it is set to emphasize the function.
     p.setSupervised(true);
     //set record route so we see the ACK, BYE, and OK
     p.setRecordRoute(true);
     //proxy on the request
     p.proxyTo(req.getRequestURI());
  }
public void doRequest(SipServletRequest req)
     throws ServletException, java.io.IOException {
   System.out.println(req.getMethod()+" Request from "+req.getFrom().getDisplayName());
   super.doRequest(req);
}
public void doResponse(SipServletResponse resp)
     throws ServletException, java.io.IOException {
   System.out.println(resp.getReasonPhrase()+" Response from "+resp.getTo().getDisplayName());
   super.doResponse(resp);
}
}

Proxy deployment descriptor
<sip-app>
    <display-name>ProxyServlet</display-name>
    <servlet>
        <servlet-name>ProxyServlet</servlet-name>
        <servlet-class>com.example.ProxyServlet</servlet-class>
    </servlet>

    <servlet-mapping>
        <servlet-name>ProxyServlet</servlet-name>
        <pattern>
              <equal>
                <var>request.method</var>
                <value>INVITE</value>
```

```
            </equal>
        </pattern>
    </servlet-mapping>
</sip-app>
```

## JSR 289 overview

Version 8.0 includes support for SIP Servlet Specification 1.1, also referred to as Java Specification Request (JSR) 289.

**Note:** Version 8.0 includes support for SIP Servlet Specification 1.1, also referred to as Java Specification Request (JSR) 289.

The SIP Servlet Specification provides the Java API standards for Session Initiation Protocol (SIP). JSR 289 is an update to the existing SIP Servlet specification that addresses new requirements determined by industry users.

SIP is a signalling protocol used for creating, modifying, and terminating IP communication sessions such as telephony and presence applications. SIP is not limited to voice communication and can mediate any kind of communication session, such as multimedia.

The following is a brief description of new features available in the JSR 289 specification.

- Application router for application selection

  Application routing enables developers to build complex services out of smaller applications. On initial requests the container calls the application router to determine which application to invoke based on the type of request. The application router is the central hub for selecting application order. See the topic on configuring a SIP application router for more information.
- Annotation-based programming

  Annotations provide a fast way to develop applications by embedding metadata directly in applications. For example, you can use the `@SipServlet` annotation to indicate that a class is a SIP servlet. The `@SipApplication` is a package level annotation. All servlets in the package belong to the same application unless the servlet uses `@SipServlet(applicationName)`. For more information on annotations, see section 18 of the JSR 289.
- Converged applications

  JSR 289 provides a new, standardized mechanism for building converged applications. A converged application contains SIP servlet components and other Java EE components, like HTTP servlets and enterprise beans. The specification includes two new classes to support convergence.
  - `ConvergedHttpSession` is an extension to HttpSession for converged applications.
  - `SipSessionUtil` handles session management for converged applications.

  For more information on converged applications, see section 13 of the JSR 289.
- Back-to-back user agent (B2BUA) APIs

  JSR 289 simplifies the B2BUA pattern in applications with the use of the B2BUA helper class. The B2BUA is a frequently used application pattern. The B2BUA acts as an endpoint for two or more dialogs and forwards requests and responses between those dialogs. The B2BUA helper has the ability to create a copy of an incoming request. It also automatically maintains links between sessions on both sides of the B2BUA. For more information on B2BUAs, see section 12 of the JSR 289.

***SIP application router:***

The SIP application router is used by the SIP container to select the order in which applications are run within the container.

The SIP container can invoke multiple applications in order to deploy a complete service or function. This modular and compositional approach makes it easier for application developers to develop new applications. The modular applications can be more easily combined and managed, while individual application implementations remain independent.

The application router is responsible for selecting the correct applications in the correct order to service an incoming message. An application router is required for a container to function, but it is a separate logical entity from the container. The application router is based on the JSR 289 specification. See the specification for more details about the application router function.

The default application router (DAR) can be configured with a standard configuration file, which is supplied to the container through a SIP container custom property, as defined in JSR 289. The DAR configuration file can also be uploaded in the administrative console for each target of the DAR.

Application routing, also referred to as application composition, can be handled in a number of ways:

- Specify the order in which the applications should run using the administrative console.
- Upload a custom application router implementation class either by specifying the path of the Java archive (JAR) file containing the application router implementation and provider through the console or adding it to the class path. A specific provider can be defined with a SIP container custom property.
- Configure the DAR by uploading its properties file and providing its location through a system property.
- Use an interactive wizard to generate a DAR configuration file.

**Restriction:** WebSphere Application Server has a default way of sorting the order of SIP applications invocation using the Startup behavior settings. The sorting order is based on the application weight. This weighting policy only applies if you do not specify a DAR property file and no custom application router has been associated with the server or cluster.

**Note:** If CEA features are used, the CEA system application requires special consideration when enabled on the same server or cluster as a custom application router. To deploy an application router and still maintain the capabilities of the CEA system application, use one of the following two options:

- Only enable CEA on an isolated server or cluster that includes no custom application router.
- Make sure the custom application router routes all CEA specific messages to the CEA system application. To do this, the developer of the application router must check the mappings that are defined in the sip.xml file associated with the CEA system application. The sip.xml file associated with the CEA system application can be found in the directory path at *app_server_root*/`systemApps`.

  The following information explains how to configure a custom application router to route to the commsvc system application. The examples show a custom application router configuration with and without the commsvc application.

  First, here is an example configuration without commsvc:

```
INVITE: ("TestB2bua", "DAR:To", "NEUTRAL", "", "NO_ROUTE", "0")
```

  The first element after the INVITE is the display name of the test application, and this one-line application router routes b2bua calls to the application successfully. With the preceding application router configured on the SIP container, however, CEA Web collaboration attempts fail.

  To enable routing to the CEA system application, just clone the routing element and change the application name in the second element instance:

```
INVITE: ("TestB2bua", "DAR:To", "NEUTRAL", "", "NO_ROUTE", "0"),("commsvc", "DAR:To", "NEUTRAL", "", "NO_ROUTE", "0")
```

  This action ensures that CEA messages are routed correctly.

***Tuning considerations using the JSR 289 Application Router with multiple applications:***

This topic describes performance adjustments and considerations using the JSR 289 Application Router with multiple applications.

**Note:** This topic references one or more of the application server log files. Beginning in WebSphere Application Server Version 8.0 you can configure the server to use the High Performance Extensible Logging (HPEL) log and trace infrastructure instead of using `SystemOut.log` , `SystemErr.log`, `trace.log`, and `activity.log` files or native z/OS logging facilities. If you are using HPEL, you can access all of your log and trace information using the LogViewer command-line tool from your server profile bin directory. See the information about using HPEL to troubleshoot applications for more information on using HPEL.

When you deploy more than one application, you might see the following errors in the log files when heavy SIP protocol traffic exists for a single application server or cluster of servers:

- Unexpected and excessive SIP application 503 Server Unavailable error messages
- Proxy and Server overload errors

**Note:** These error messages do not occur when you deploy one application.
The proxy server and Session Initiation Protocol (SIP) containers are not synchronized when they are tracking the amount of messages that are flowing through the system. Using the application router, multiple messages might be routed between applications. These messages cause container message counters to increment even though the messages do not flow through the proxy server.

You can diagnose this problem when you have the following conditions:

- Heavy SIP protocol traffic exists.
- Multiple applications are deployed on a single node or cluster.

Check the proxy server, the application server SystemOut.log log files, or both for an unexpected overload condition that is detected at the proxy server, the application server, or both. Also, look for 503 Server unavailable messages that are logged from the SIP application.

**Resolving the problem**

Messages are shared between applications at the SIP container before they are sent to the proxy server. To avoid these error messages and a decrease in SIP performance, tune the SIP containers to consider the additional SIP messages that are generated when using the application router with multiple applications. Complete the following steps in the administrative console to tune the SIP containers:

1. Expand **Servers** > **Server Types** and click **WebSphere application servers** > ***server_name***
2. Under **Container Settings**, expand **SIP Container Settings** and click **SIP container**.
3. Increase the **Maximum messages per averaging period** value to compensate for the anticipated increase in messages that are generated by the SIP application router.
4. Increase the **Maximum application sessions** value to compensate for the increased **Maximum messages per averaging period** value.

The proxy server cannot detect the amount of messages that are generated at the server. However, modifications to the following settings might increase the messaging capacity at the containers for the number of applications that are deployed per container.

*Table 163. DAR and CAR SIP container tuning values.*

*This table lists the DAR and CAR SIP container tuning values for the number of applications that are deployed per container.*

| SIP Container | Single Deployed SIP Application | Three Deployed SIP Applications |
|---|---|---|
| Maximum messages per averaging period | value = 26640 | value = 79920 |
| Maximum application sessions | value = 36000 | value = 96000 |

**Note:** The values for the **Maximum messages per averaging period** and **Maximum application sessions** fields depend on the processing power, memory, and the deployed application. Use the values for these fields as listed in the SIP container settings topic and adjust them to meet the needs of your environment.

# Developing applications that use the Asynchronous Invocation API

You can use the Asynchronous Invocation API to transfer events that require processing in the context of a Session Initiation Protocol (SIP) application session to any server in a cluster based on the related application session ID. The Asynchronous Invocation API transfers the event task to the correct server.

## Before you begin

Read the API documentation for information on the following asynchronous work classes:

- com.ibm.websphere.sip.AsynchronousWork
- com.ibm.websphere.sip.AsynchronousWorkListener

For more information about the API classes, see the Reference section in the information center and click APIs - Application Programming Interfaces to view a list of the product API specifications.

## About this task

When running code outside of a SIP thread, application developers can use the Asynchronous Invocation API to create an object, and configure the server to run that object either on a different thread in the same container, or on a different server, if that is where the session exists.

The following example shows the class structure for the AsynchronousWork class, which is the abstract base class that is extended when using the API.

```
public abstract class AsynchronousWork implements Serializable
{
private String sessionId;
public AsynchronousWork(String sessionId)
{
this.sessionId = sessionId;
....
}
public void dispatch (AsynchronousWorkListener listener)
{
....
}
public abstract Serializable doAsyncTask();
}
```

## Procedure

1. Extend the abstract class AsynchronousWork with the SIP related code. The extended implementation of the doAsyncTask() method is invoked on the target server that contains the SipApplicationSession, and whose ID was set in the constructor that implements the AsynchronousWork class. The implementation class must pass the session ID to the base class by calling super in the constructor.

   ```
   public class MyClass extends AsynchronousWork
   {
   String _sessionId;

   public MyClass(String sessionId) {
   super(sessionId);
   _sessionId = sessionId;
   }

   // This code is invoked on the target machine or thread
   public Serializable doAsyncTask() {
   ```

```
// Application code goes here; for instance:
appSession = sessionUtils.getApplicationSession(_sessionId);
appSession.createRequest().....

Serializable myResponse = new MyResponse();
myResponse.setStatus(200);
return (myResponse);
}
}
```

2. To receive information about the task completion, implement the AsynchronousWorkListener class, as in the following example. The code in these methods are invoked on the source server.

```
public class MyListener implements AsynchronousWorkListener
{
public void workCompleted(Serializeable myResponse)
{
....
}
public void workFailed(int reasonCode, String reason)
{
}
}
```

3. To invoke the asynchronous call; for example, when you receive the proprietary message, use this sample code as an example.

```
public void onMyMessage()
{
// Obtain the session ID from the message or
// somewhere else
String sessionId = obtainIdFromMessage();

// Create the runnable
MyClass myClass = new MyClass(sessionId);

// Create the listener
MyListener myListener = new MyListener();

// Dispatch it
myClass.dispatch(myListener);
}
```

## Results

The SIP container ensures the task is invoked in the correct server and on the correct thread, so that the application can avoid synchronization on the session level.

## Asynchronous Invocation API

Use the Asynchronous Invocation API to transfer events that require processing in a Session Initiation Protocol (SIP) application session to any server in a cluster based on an application session ID.

The Asynchronous Invocation API, also referred to as the asynchronous work dispatcher, can transfer events that require processing in the context of a SIP application session to any server in a cluster, using the related application session ID. These transfers are usually triggered by events that cause a state change to SIP sessions that reside on another server. The asynchronous work dispatcher transfers the event task to the correct server to be run.

In Websphere Application Server, all related SIP messages are delivered to the same server in the cluster, and sessions always reside in the same SIP container. To prevent synchronicity issues and locking, tasks in the same application session cannot be processed simultaneously (that is, on different threads or processes), which limits handling of certain types of events.

For more in-depth information about SIP sessions and SIP application sessions and their relationship, see Section 6 of Java Specification Request (JSR) 289.

The following two scenarios are resolved by implementing the Asynchronous Invocation API.

1. Two requests related to the same SIP application session are simultaneously run on two different threads. For example, a Java EE (J2EE) applications working with a message-driven bean (MDB) can retrieve an event to send a SIP message on a certain SIP application session. At the same time, the SIP container receives an incoming SIP message on another session that is connected to the same application session and handles that on a different thread. It would be necessary to synchronize the session access to avoid race conditions and to ensure that all session attributes are synchronized. To employ the locking mechanism in this case would not be effective, because the SIP application session might contain multiple SIP sessions.
2. A server that does not own a certain SIP application session receives a request, through non-SIP protocol, to send a message in the context of that session. For example, a Web service that is initiating SIP dialogs can reside in a server different from the server that owns the SIP application session it must use.

The Asynchronous Invocation API ensures that the specific application code is run on the correct server and correct thread according to the SIP application session ID.

The Asynchronous Invocation API provides the following benefits:

1. No more than two servers are involved in the asynchronous invocation process: one is the server that retrieves the work task, and the other is the target server that handles the SIP application session for that task and to which the task will be transferred.
2. The asynchronous invocation allows working in a thread-safe manner. This approach ensures that only one thread processes the messages related to the SIP application session. Thus, there is no need to synchronize access to the session.
3. The asynchronous invocation provides a scalable solution. There is no performance impact when more servers are added to the cluster.
4. Cross-server invocation is used only when required, which results in better performance.

# Deploying SIP applications

Use the administrative console to customize your Session Initiation Protocol (SIP) application installation

## About this task

When you deploy a Session Initiation Protocol (SIP) application, you can perform various tasks such as installing, starting, stopping, upgrading, and uninstalling the application.

SIP applications are installed as Java Platform, Enterprise Edition (Java EE) applications. You can deploy a SIP application from a graphical interface or from a command line.

# Deploying SIP applications through the console

You can deploy a Session Initiation Protocol (SIP) application through the administrative console.

## Before you begin

SIP applications are deployed as Java 2 Platform Enterprise Edition (J2EE) applications. In order to process requests, a virtual host must be defined when deploying the SIP application. If there is no virtual host defined for the configured SIP container listen port, the installed application will be inaccessible.

## Procedure

1. Open the administrative console.

In a browser, go to URL `http://hostname:9090/admin`, where *hostname* is the name of the host computer. Enter the appropriate login information, and click **OK**.

2. In the left frame click **Applications** > **Install New Application**.
3. Browse and select a SAR file. Specify the context root, beginning with a slash (/), in the **Context Root** field. For example, if your application is named ThisApplication, type `/ThisApplication`.
4. Click **Next** (under the **Context Root** field not beside the WebSphere Status title). If the SAR file has been assembled correctly, the screen will still have the title “Preparing for the application installation”, but the content will change. If an error message appears, check the contents of the SAR file; in particular, verify the `web.xml` file contents, and try to reload the SAR file.
5. Click **Next**. If you see a screen indicating “Application Security Warnings”, click **Continue**.
6. The **Install New Application** screen should appear with “Step 1: Select application options” highlighted. Select the options you need and click **Next**.
7. “Step 2: Map modules to servers” should appear highlighted now. You can choose the cluster or server where you want to install the application's modules.
   - If you are installing the application in a stand-alone system, click **Next**.
   - If you are installing the application in a clustered system, select **WebSphere:cell=*cellname*,cluster=*cluster_name*** in the **Clusters and Servers** field, select the check box beside the web module that you want to install, and click **Apply** and **Next**.
8. Now “Step 3: Map virtual hosts for web modules” should appear highlighted. To the right of the application name there should be a drop-down labeled **Virtual Host**.
   - If you are installing the application in a stand-alone system, set the value of the drop-down to **default_host**, and click **Next**.
   - If you are installing the application in a clustered system, set the value of the drop-down to the name of the virtual host that was chosen during setup, and click **Next**.

   **Remember:** You must define a virtual host for your configured SIP container listen port or else you will not be able to access the application.
9. You should now see “Step 4: Summary” highlighted. In the right panel you will see a **Summary of installation options** table that details your selected options and their values. If you need to change an option, click **Previous** to return to the section where you can make your change. Click **Finish** to install the application with your settings. The screen should display, `Application appname_sar installed successfully`, where *appname* is the name of the application.
10. Click the **Save to Master Configuration** link. A Save to Master Configuration window appears.
11. In the Save to Master Configuration window, click **Save**. The application has now been saved in the current configuration.
12. To confirm that the installation succeeded, in the left frame click **Applications** > **Enterprise Applications**. The newly installed application should appear in the list of installed applications as *appname*_sar.
13. To start the application so that it can service SIP requests, check the box beside *appname*_sar, and click **Start**. You might also want to look at the logs for a successful startup message.

### Results

The application can service SIP requests now.

## Deploying SIP applications through scripting

You can deploy a Session Initiation Protocol (SIP) application not only from the administrative console but also from a command line.

## About this task

**Note:** To deploy a SIP application, the application must exist with an enterprise archive (EAR) file, a Session Initiation Protocol (SIP) module (SAR file), or a web application archive (WAR) file.

Use the wsadmin scripting tool to deploy applications from a command line.

## Procedure

- Launch a scripting client.

  For more information, see AdminApp object for scripted administration.
- List applications.

  For more information, see Listing applications using the wsadmin scripting tool.
- Install stand-alone archive files.

  For more information about installation, see Installing enterprise applications using wsadmin scripting and Installation options for the AdminApp object.
- Edit application configurations.

  For more information, see Editing application configurations using the wsadmin scripting tool.
- Uninstall applications.

  For more information, see Uninstalling enterprise applications using the wsadmin scripting tool.

# Chapter 30. Developing Spring applications

This page provides a starting point for finding information about how to develop Spring applications that can run successfully in a WebSphere Application Server environment.

The Spring Framework is an open source project that provides a framework for simple Java objects that enables them to use the Java EE container through wrapper classes and XML configuration.

## Configuring access to a Spring application data source

You can use WebSphere Application Server to manage access to a data source for a Spring application.

### About this task

For a Spring application to access a data source, such as a Java Database Connectivity (JDBC) data source, the application must use a resource provider that is managed by the WebSphere Application Server. For more information about Spring applications and the Spring Framework see the following topics:

- Spring Framework
- Data access and the Spring Framework

### Procedure

1. During development, configure the WAR module with a resource reference. For example:

```
<resource-ref>
    <res-ref-name>jdbc/springdbres-ref-name>jdbc/springdb>
    <res-type>javax.sql.DataSourceres-type>javax.sql.DataSource>
    <res-auth>Containerres-auth>Container>
    <res-sharing-scope>Shareableres-sharing-scope>Shareable>
</resource-ref>
```

2. For Enterprise JavaBeans (EJB) Java archive (JAR) files, declare the same resource reference in each EJB that needs to access the data source. Use one of the following steps:
   - Declare a data source proxy bean. In the Spring application configuration, declare a proxy bean that references a resource provider that the application server manages. Set the value of the jndiName property to java:comp/env/ followed by the value of res-ref-name property that you declared in the resource reference. For example:

```
<bean id="wasDataSource" class="org.springframework.jndi.JndiObjectFactoryBean">
    <property name="jndiName" value="java:comp/env/jdbc/springdb"/>
    <property name="lookupOnStartup" value="false"/>
    <property name="cache" value="true"/>
    <property name="proxyInterface" value="javax.sql.DataSource"/>
</bean>
```

   - Alternatively, for Spring Framework Version 2.5 or later, use the <j2ee:jndi-lookup/> approach. Set the value of the jndi-name property to the value of the res-ref-name property that you declared in the resource reference, and the value of the resource-ref property to `true`. For example:

```
<jee:jndi-lookup id=" wasDataSource "
    jndi-name="jdbc/springdb"
    cache="true"
    resource-ref="true"
    lookup-on-startup="false"
    proxy-interface="javax.sql.DataSource"/>
```

   The Spring application can then use the data source proxy bean as appropriate.
3. When the application is deployed to an application server, configure a resource provider and resource data source that the Spring application resource reference can use.

© Copyright IBM Corp. 2011

## Results

The resource reference that is declared in the deployment descriptor of the module will be bound to the configured data source of the application server during deployment.

# Chapter 31. Developing Transactions

This page provides a starting point for finding information about Java Transaction API (JTA) support. Applications running on the server can use transactions to coordinate multiple updates to resources as one unit of work, such that all or none of the updates are made permanent.

The product provides advanced transactional capabilities to help application developers avoid custom coding. It provides support for the many challenges related to integrating existing software assets with a Java EE environment. More introduction...

## Developing components to use transactions

These topics provide information about developing WebSphere application components to use transactions

### About this task

The way that applications use transactions depends on the type of application component, as follows:

- A session bean can either use container-managed transactions (where the bean delegates management of transactions to the container) or bean-managed transactions (component-managed transactions where the bean manages transactions itself).
- Entity beans use container-managed transactions.
- Web components (servlets) and application client components use component-managed transactions.

Use the following tasks to develop WebSphere application components that use transactions:

### Procedure

- Configure transactional deployment attributes. This task determines whether EJB components use container- or bean-managed transactions by setting an appropriate value on the Transaction type deployment attribute. You can also configure other transactional deployment descriptor attributes.
- Use component-managed transactions. If you want a session bean, web component, or application client component to manage its own transactions, you must write the code that explicitly demarcates the boundaries of a transaction. There are some limitations to the transaction support available to application client components, as described in the topic about client support for transactions.

## Configuring transactional deployment attributes

You can configure the transactional deployment descriptor attributes associated with an EJB or web module, to enable an enterprise application to use transactions.

### Before you begin

You must have an enterprise archive (EAR) file for an application component that can be deployed in the application server.

### About this task

You can configure the deployment attributes of an application by using an assembly tool.

You can use Rational Application Developer, or an equivalent tool, to configure the deployment attributes of an application.

To use Rational Application Developer to set transactional attributes in the deployment descriptor for an application component (enterprise bean or servlet), complete the following steps.

© IBM Corporation 2009

## Procedure

1. Start the assembly tool. For more information, refer to the Rational Application Developer information.
2. Create or edit the application EAR file. For example, to change attributes of an existing application, use the Import wizard to import the EAR file into the assembly tool. To start the Import wizard:
   a. Click **File** > **Import** > **EAR file**.
   b. Click **Next**, then select the EAR file.
   c. Click **Finish**.
3. In the Project Explorer view of the Java EE perspective, right-click the component instance, then click **Open With** > **Deployment Descriptor Editor**. To locate the component instance, use the appropriate step:
   - For a session bean, expand **EJB Modules** > ***ejb_module_instance*** > **Deployment Descriptor** > **Session Beans**, then select the bean instance.
   - For a servlet, expand **Web Modules** > ***web_application*** > **Deployment Descriptor** > ***web component***, then select the servlet instance.

   A property dialog notebook for the deployment descriptor of the component is displayed in the property pane.
4. Optional: For session beans only, set the “Transaction type” attribute, which defines the transactional manner in which the container invokes a method. You can set this attribute to Container or Bean, as follows:
   - To use container-managed transactions, set the attribute to Container.
   - To use bean-managed transactions, set the attribute to Bean.
5. In the deployment descriptor notebook, select the **Bean** tab. Optionally, in the WebSphere Extensions section, configure the Local Transaction attributes. To enable management of local transaction containments, configure the following component extensions attributes. These attributes configure, for the component, the behavior of the local transaction containment (LTC) environment that the container establishes whenever a global transaction is not present.

   **Boundary**

   This setting specifies the containment boundary at which all contained resource manager local transactions (RMLTs) must be completed. Possible values are BeanMethod or ActivitySession.
   - BeanMethod: This is the default value. If you select this option, RMLTs must be resolved within the same bean method in which they were started.
   - [For EJB components only] ActivitySession: RMLTs must be resolved within the scope of any ActivitySession in which they were started or, if no ActivitySession context is present, within the same bean method in which they were started.

     **Note:** The ActivitySession option is not supported in the web container.

   **Resolver**

   This setting specifies the component responsible for initiating and ending RMLTs. Possible values are Application or ContainerAtBoundary.
   - Application: This is the default value. The application is responsible for starting RMLTs and for completing them within the local transaction containment (LTC) boundary. Any RMLTs that are not completed by the end of the LTC boundary are cleaned up by the container according to the value of the Unresolved action attribute.
   - ContainerAtBoundary: The container is responsible for starting RMLTs and for completing them within the LTC boundary. The container begins an RMLT when a connection is first used within the LTC scope, and completes it automatically at the end of the LTC scope. If Boundary is set to ActivitySession, the RMLTs are enlisted as ActivitySession resources and directed to complete by the ActivitySession. If Boundary is set to BeanMethod, the RMLTs are committed at the end of the method by the container.

   **Unresolved action**

Specifies the direction that the container requests RMLTs to take, if those transactions are unresolved at the end of the LTC boundary scope and the Resolver is set to Application. Possible values are Rollback or Commit.

- Rollback: This is the default value. At end of the LTC boundary scope, the container instructs all unresolved RMLTs to roll back.
- Commit: At the end of the LTC boundary scope, the container instructs all unresolved RMLTs to commit. The container instructs the RMLTs to commit only in the absence of an un-handled exception. If the application method that is running in the local transaction context ends with an exception, any unresolved RMLTs are rolled back by the container. This is the same behavior as for global transactions.

**Shareable**

Specifies whether the component can share an LTC. A new LTC is started only if a shareable LTC does not already exist. Applications that use shareable LTCs cannot explicitly commit or roll back resource manager connections that are used in a shareable LTC (although they can use connections that have an autoCommit capability).

If an application starts any non-autocommit work in an LTC for which the Resolver attribute is set to `Application`, and the Shareable attribute is set to `true`, an exception is thrown at run time. For example, on a JDBC Connection, non-autocommit work is work that the application performs after using the setAutoCommit(false) method to switch off the autocommit option on the connection. Enterprise beans that use bean managed transactions (BMT) cannot be assembled with the Shareable attribute set on the LTC configuration.

You must specify the **Shareable** attribute for all components that share the LTC. The component that creates the shareable LTC determines the other properties of the shared LTC, for example the value of the Resolver attribute.

6. In the WebSphere Extensions section, configure the Global Transaction attributes. These attributes configure, for the component, behavior in the presence of a global transaction.

**Component Transaction Timeout**

For enterprise beans that use container-managed transactions only, specifies the transaction timeout, in seconds, for any new global transaction that the container starts on behalf of the enterprise bean. For transactions started on behalf of the component, the Component Transaction Timeout setting overrides the default total transaction lifetime timeout that is configured in the transaction service settings for the application server.

The following attributes enable WS-AtomicTransaction and WS-BusinessActivity support for JAX-RPC applications only:

**Use Web Services Atomic Transaction**

For enterprise beans only, when this attribute is selected, if the application component makes any web service requests, any transaction context is propagated with the web service requests in accordance with the WebSphere WS-AtomicTransaction support described in Web Services Atomic Transaction support in the application server. When this attribute is not selected, web service requests do not carry transaction context.

**Send Web Services Atomic Transaction on requests**

For web components only, when this attribute is selected, if the application component makes any web service requests, any transaction context is propagated with the web service requests in accordance with the WebSphere WS-AtomicTransaction support described in Web Services Atomic Transaction support in the application server. When this attribute is not selected, web service requests do not carry transaction context.

**Execute using Web Services Atomic Transaction on incoming requests**

For web components only, when this attribute is selected, Web application components are prepared to run under a received WS-AtomicTransaction context. A web application component can run under a received WS-AtomicTransaction context in a similar way to an enterprise bean deployed with a container transaction type of Supports. When this attribute is not selected, the container of the web application component suspends any received

transaction context, in a similar way to the behavior of an EJB container for an enterprise bean deployed with a container transaction type of NotSupported.

If your application uses JAX-WS, enable support for WS-AtomicTransaction or WS-BusinessActivity by creating a policy set, adding the WS-Transaction policy type to the policy set, and attaching the policy set to the service or client.

If a policy set that is attached to a client includes the WS-Transaction policy type, any active global transaction context is propagated with a Web service request, in a similar way to the deployment descriptors Use Web Services Atomic Transaction and Send Web Services Atomic Transaction on requests, described earlier in this topic. Also, when the WS-Transaction policy type is included, the service runs under any received WS-AtomicTransaction context, in a similar way to the deployment descriptor Execute using Web Services Atomic Transaction on incoming requests, described earlier in this topic.

7. For EJB components only, for container-managed transactions, configure how the container manages the transaction boundaries when delegating a method invocation to the business method of an enterprise bean:
   a. In the deployment descriptor notebook, select the **Assembly** tab. The Container Transactions section displays a table of the methods for enterprise beans.
   b. For each method of the enterprise bean, set the container transaction type to an appropriate value. The default value for the container transaction type is Required, meaning that the method invocation occurs in the context of a transaction. This transaction is either the (local or remote) client component transaction or, if the client component does not run in a transaction, a new transaction started by the component container.

   If the application uses ActivitySessions, how the container manages transaction boundaries when delegating a method invocation depends on both the container transaction type that you set in this task, and the ActivitySession kind attribute, which is described in “Setting EJB module ActivitySession deployment attributes” on page 4. For more detail about the relationship between these two properties, see ActivitySession and transaction container policies in combination.
8. For web services applications that use a SOAP/JMS binding and participates in WS-AtomicTransactions, set the container transaction type of the message-driven bean named “JMS router MDB” to a value of NotSupported, as described in the previous step. Web service applications that use a SOAP/JMS binding include a router message-driven bean named “JMS router MDB” in the assembled EAR. If a web service uses a SOAP/JMS binding and participates in WS-AtomicTransactions, as described in Web Services Atomic Transaction support in the application server, set the container transaction type of the “JMS router MDB” to a value of NotSupported.

   For web services applications that use a SOAP/HTTP binding and participate in WS-AtomicTransactions, you do not have to do this.
9. For client application components only, if required, enable support for transaction demarcation by the client. In the deployment descriptor notebook, select the **Allow JTA demarcation** check box. This option directs the client container to bind the Java Transaction API (JTA) UserTransaction interface into JNDI at java:comp/UserTransaction for the client component. There are constraints on transaction support in the client container, which are described in Client support for transactions.
10. Save your changes to the deployment descriptor.
    a. Close the deployment descriptor editor.
    b. When prompted, click **Yes** to save changes to the deployment descriptor.
11. Verify the archive files. For more information about verifying files by using Rational Application Developer, refer to the Rational Application Developer information.
12. From the menu of the project, click **Deploy** to generate EJB deployment code.
13. Optional: Test your completed module on an application server installation. Right-click a module, click **Run on Server**, and follow the instructions in the resulting wizard.

**Important:** Use the **Run On Server** option for unit testing only. The assembly tool controls the application server installation, and when an application is published remotely, the assembly tool overwrites the server configuration file for that server. Do not use the **Run On Server** option on production servers.

### What to do next

After assembling your application, use a systems management tool, for example the administrative console, to deploy the EAR file onto the application server that is to run the application.

## Using component-managed transactions

You can enable a session bean, servlet, or application client component to use component-managed transactions, to manage its own transactions directly instead of letting the container manage the transactions.

### About this task

**Note:** Entity beans cannot manage transactions (so cannot use bean-managed transactions).

To enable a session bean, servlet, or application client component to use component-managed transactions, complete the following steps:

### Procedure

1. For session beans, set the **Transaction type** attribute in the component deployment descriptor to Bean, as described in "Configuring transactional deployment attributes" on page 1341.
2. For application client components, enable support for transaction demarcation by setting the **Allow JTA Demarcation** attribute in the component deployment descriptor, as described in "Configuring transactional deployment attributes" on page 1341.
3. Write the component code to actively manage transactions.

   For stateful session beans, a transaction started in a given method does not have to be completed (that is, committed or rolled back) before completing that method. The transaction can be completed at a later time, for example on a subsequent call to the same method, or even within a different method. However, it is usually preferable to construct the application so that a transaction is begun and completed within the same method call, because it simplifies application debugging and maintenance.

   The following code extract shows the standard code required to obtain an object encapsulating the transaction context, and involves the following steps:
   - Create a javax.transaction.UserTransaction object by calling a lookup on java:comp/UserTransaction.
   - Use the UserTransaction object to demarcate the boundary of a transaction by using transaction methods such as begin and commit, as needed. If an application component begins a transaction, it must also complete that transaction by invoking either the commit method or the rollback method.

   **Code example: Getting an object that encapsulates a transaction context**

```
...
import javax.transaction.*;
import javax.naming.InitialContext;
import javax.naming.NamingException;
...
    public float doSomething(long arg1)throws NamingException {
        InitialContext initCtx = new InitialContext();
        UserTransaction userTran = (UserTransaction)initCtx.lookup(
           "java:comp/UserTransaction");
        ...
        //Use userTran object to call transaction methods
        userTran.begin ();
        //Do transactional work
        ...
        userTran.commit ();
```

```
        ...
    }
    ...
}
```

# Using one-phase and two-phase commit resources in the same transaction

Use these topics to help you coordinate the use of a single one-phase commit capable resource with any number of two-phase commit capable resources in the same global transaction.

## About this task

You can coordinate the use of a single one-phase commit capable resource with any number of two-phase commit capable resources in the same global transaction. You can have multiple interactions that involve the one-phase commit resource in the same transaction, but only one such resource can be involved. This coordination is enabled by the *last participant support*.

At transaction commit, the two-phase commit resources are prepared first using the two-phase commit protocol, and if this is successful the one-phase commit-resource is then called to commit. The two-phase commit resources are then committed or rolled back depending on the response of the one-phase commit resource.

For more information about using one-phase and two-phase commit resources within the same transaction, see the following topics:

## Procedure

- “Approaches to coordinating access to one-phase commit and two-phase commit capable resources in the same transaction” on page 1348
- “Assembling an application to use one-phase and two-phase commit resources in the same transaction”
- Configuring an application server to log heuristic reporting

## Assembling an application to use one-phase and two-phase commit resources in the same transaction

Use this task to assemble an application to use one-phase and two-phase commit resources in the same transaction.

### Before you begin

This task description assumes that you have an EAR file for an application component that can be deployed in WebSphere Application Server. For more details about assembling applications, see the topic about assembling applications.

### About this task

To enable an application to use one-phase and two-phase commit capable resources in the same transaction, you must configure the deployment attributes of the application to accept the heuristic hazard, that is, the increased risk of an heuristic outcome. You can configure the deployment attributes of an application by using an assembly tool.

You can also configure an application to accept the heuristic hazard after deployment, by using the administrative console and the Last participant support extension settings. Alternatively, you can configure the transaction service for an application server to accept the heuristic hazard.

This topic describes the use of Rational Application Developer to configure the deployment attributes of an application.

To configure an application to indicate that you accept the increased risk of an heuristic outcome, complete the following steps:

## Procedure

1. Start the assembly tool. For more information, refer to the Rational Application Developer information.
2. Create or edit the application EAR file.

   **Note:** Ensure that you set the target server as WebSphere Application Server Version 7.0.

   For example, to change attributes of an existing application, use the Import wizard to import the EAR file into the assembly tool. To start the Import wizard:

   a. Click **File** > **Import** > **EAR file**.
   b. Click **Next**, then select the EAR file.
   c. In the Target server field, select `WebSphere Application Server v7.0`.
   d. Click **Finish**.
3. In the Project Explorer view of the Java EE perspective, complete the following steps:
   a. Expand the Enterprise Application instance.
   b. Right click on the Deployment Descriptor.
   c. Click **Open With** > **Deployment Descriptor Editor**.

   A property dialog notebook for the component is displayed in the property pane.
4. Complete the following steps to display the Extended Services tab.
   a. Close the Enterprise Application Deployment Descriptor editor.
   b. In the toolbar, select **Windows** > **Preferences**.
   c. In the left pane, select **Capabilities**.
   d. In the right pane, expand **Advanced Java EE** and select the **WebSphere PME Development** option.
   e. Click **Apply**.
   f. Open the Enterprise Application Deployment Descriptor editor.
5. On the Extended Services tab, in the Last Participant Support section, select the **Last participant support** check box.
6. Save your changes to the deployment descriptor.
   a. Close the Deployment Descriptor Editor.
   b. When prompted, click **Yes** to save changes to the deployment descriptor.
7. Verify the archive files. For more information about verifying files using Rational Application Developer, refer to the Rational Application Developer information.
8. From the popup menu of the project, click **Deploy** to generate EJB deployment code.
9. Optional: Test your completed module on a WebSphere Application Server installation. Right-click a module, click **Run on Server**, and follow the instructions in the displayed wizard.

   **Important:** Use **Run On Server** only for unit testing. The assembly tool controls the WebSphere Application Server installation and, when an application is published remotely, the assembly tool overwrites the server configuration file for that server. Do not use the **Run On Server** option on production servers.

## What to do next

After assembling your application, use a systems management tool to deploy the EAR file onto the application server that is to run the application; for example, using the administrative console, as described in the topic about deploying and administering enterprise applications.

***Last participant support extension settings:***

Use this page to configure settings for last participant support. Last participant support is an extension to the transaction service that enables a single one-phase resource to participate in a two-phase transaction with one or more two-phase resources. Values on this panel are ignored if you select **Use configuration information in binary** on the Application binaries panel.

To view this administrative console page, click **Applications > Application Types > WebSphere enterprise applications >** *application_name*. Under **Detailed Properties**, click **Last participant support extension**.

*Accept heuristic hazard:*

Specifies whether an application accepts the possibility of a heuristic hazard occurring in a two-phase transaction that contains a one-phase resource.

**Default**
Cleared

**Range**

**Selected**
The application accepts the increased risk of an heuristic outcome.

**Cleared**
The application does not accept the increased risk of an heuristic outcome.

## Approaches to coordinating access to one-phase commit and two-phase commit capable resources in the same transaction

Last participant support enables the use of a single one-phase commit capable resource with any number of two-phase commit capable resources in the same global transaction. You can have multiple interactions that involve the one-phase commit resource in the same transaction, but only one such resource can be involved.

At transaction commit, the two-phase commit resources are prepared first using the two-phase commit protocol, and if this is successful, the one-phase commit-resource is then called to commit. The two-phase commit resources are then committed or rolled back, depending on the response of the one-phase commit resource.

Last participant support introduces an increased risk of an heuristic outcome to the transaction. That is, the transaction manager cannot be sure that all resources were completed in the same direction (either committed or rolled back). For this reason, to enable an application to coordinate access to one-phase and two-phase commit capable resources in the same transaction, you configure the application to accept the heuristic hazard, that is, accept the increased risk of an heuristic outcome.

An heuristic outcome occurs if the transaction service (JTS) receives no response from the commit one-phase flow on the one-phase commit resource. In this situation, the transaction service cannot determine whether changes for the one-phase commit resource were committed or rolled back, so cannot drive reliably the correct outcome of the global transaction on the other two-phase commit resources.

You can configure the transaction service for an application server to accept the heuristic hazard, or you can configure applications individually to accept the heuristic hazard. You can configure applications individually either when they are assembled, or after they are deployed.

You can configure the transaction service for an application server to indicate whether or not to log that it is about to commit the one-phase commit resource. This does not reduce the heuristic hazard, but ensures that any failure, and subsequent recovery, of the application server during the one-phase commit phase occurs with knowledge of whether or not the one-phase commit resource was asked to commit:

- If the one-phase commit resource was asked to commit, a heuristic outcome is reported to the activity log.
- If the one-phase commit resource was not asked to commit, then the transaction is rolled back consistently.

***Last Participant Support: Resources for learning:***

Use the links in this topic to find relevant supplemental information about Last Participant Support. The information resides on IBM and non-IBM Internet sites, whose sponsors control the technical accuracy of the information.

These links are provided for convenience. Often, the information is not specific to the IBM WebSphere Application Server product, but is useful all or in part for understanding the product. When possible, links are provided to technical papers and Redbooks that supplement the broad coverage of the release documentation with in-depth examinations of particular product areas.

**Programming specifications**
- J2EE Activity Service for Extended Transactions
- Java Transaction API (JTA) 1.0.1

**Other**
- WebSphere Business Integration Server Foundation
- List of IBM WebSphere Redbooks
- WebSphere technical library, including links to white papers

# Chapter 32. Developing web applications

This page provides a starting point for finding information about web applications, which are comprised of one or more related files that you can manage as a unit, including:

- HTML files
- Servlets can support dynamic web page content, provide database access, serve multiple clients at one time, and filter data.
- Java ServerPages (JSP) files enable the separation of the HTML code from the business logic in web pages.

IBM extensions to the JSP specification make it easy for HTML authors to add the power of Java technology to web pages, without being experts in Java programming. More introduction...

## Developing web applications

Learn about selecting tools for developing web applications.

### Before you begin

Design a web application and the required components.

### About this task

There are two basic approaches to selecting tools for developing web applications:

- You can use one of the available integrated development environments (IDEs). IDE tools automatically generate significant parts of the servlet and JavaServer Pages (JSP) code, and Hypertext Markup Language (HTML) files. They also contain integrated tools for packaging and testing the web application components.
- If you decide to develop web components without an IDE, you need at least an ASCII text editor. You can also use tools available in the Java SE Development Kit 6 and in this product to assemble, test, and deploy the Web application components.

The following steps support the second approach, development without an IDE.

### Procedure

1. If necessary, migrate any pre-existing code to the required version of the servlet and JSP specification.
2. Write and compile the components of the web application. To access classes that were extended, compile your code using the `-classpath` option on the `javac` compiler. This option allows you to reference the `j2ee.jar` file in the product directory:
   - *<install_root>*`\dev\JavaEE`

   Windows For example, to compile a servlet for WebSphere Application Server on Windows, specify:

   ```
   javac -classpath D:\Program Files\WebSphere\AppServer\dev\JavaEE\j2ee.jar MyServlet.java
   ```
3. Optionally disable JavaServer Pages (JSP) runtime compilation, if necessary.

### What to do next

Assemble the application components in one or more web modules.

© Copyright IBM Corp. 2011

# Developing servlets

## Developing servlets with WebSphere Application Server extensions

Use this task to provide a summary of the WebSphere Application Server extensions that you can use to develop servlets.

### About this task

Several WebSphere Application Server extensions are provided for enhancing your servlets. This task provides a summary of the extensions that you can utilize.

### Procedure

1. Review the supported specifications.

   Create Java components, referring to the Servlet specifications from Sun Microsystems.

   The application server includes its own packages that extend and add to the Java Servlet Application Programming Interface (API). These extensions and additions make it easier to manage session states, create personalized Web pages, generate better servlet error reports, and access databases. Locate the API documentation for the application server APIs in the `install_root\web\apidocs` directory for the default installation. All of the public Application Server APIs are located in the `com.ibm.websphere` packages, however, com.ibm.websphere.servlet package is specific to the product servlet APIs.
2. Use your favorite integrated development environment (IDE), or a text editor, to develop or migrate code artifacts that meet the specifications.
3. Test the code artifacts.

### What to do next

Assemble your code artifacts into a web module using assembly tools as a prerequisite to deploying the code to the application server.

#### *Configuring page list servlet client configurations:*

You can define PageListServlet configuration information in the IBM Web Extensions file. The IBM Web Extensions file is created and stored in the web applications archive (WAR) file by an assembly tool.

#### About this task

**Attention:** The PageList Servlet custom extension is deprecated in WebSphere Application Server Version 8.0 and will be removed in a future release. Re-architect your legacy applications to use javax.servlet.filter classes instead of com.ibm.servlet classes. Starting from the Servlet 2.3 specification, javax.servlet.filter classes you can intercept requests and examine responses. You can also use javax.servlet.filter classes to achieve chaining functionality, as well as embellishing or truncating responses.

To configure and implement page lists:

#### Procedure

1. To configure page list information, use the Add Markup Language entry dialog of an assembly tool. On the Servlets tab of a web deployment descriptor editor, select a servlet and click **Add** under WebSphere Extensions.
2. Add the `callPage()` method to your servlet to invoke a JavaServer Page (JSP) file in response to a client request.

   The PageListServlet has a `callPage()` method that invokes a JSP file in response to the HTTP request for a page in a page list. The `callPage()` method can be invoked in one of the following ways:

- `callPage(String pageName, HttpServletRequest request, HttpServletResponse response)`

  where the method arguments are:

  **pageName**
  A page name defined in the PageListServlet configuration

  **request**
  The HttpServletRequest object

  **response**
  The HttpServletResponse object
- `callPage(String mlName, String pageName, HttpServletRequest request, HttpServletResponse response)`

  where the method arguments are:

  **mlName** A markup language type

  **pageName**
  A page name defined in the PageListServlet configuration

  **request**
  The HttpServletRequest object

  **response**
  The HttpServletResponse object

3. Use the PageList Servlet client type detection support to determine the markup language type a calling client requires for the response.

### Extending PageListServlet

The following example shows how a servlet extends the PageListServlet class and determines the markup-language type required by the client. The servlet then uses the callPage method to call an appropriate JavaServer Pages (JSP) file. In this example, the JSP file that provides the correct markup-language for the response is *Hello.page*.

```
public class HelloPervasiveServlet extends PageListServlet implements Serializable
{
     /*
     * doGet -- Process incoming HTTP GET requests
     */
    public  void doGet(HttpServletRequest request, HttpServletResponse response)
    throws IOException, ServletException
    {
       // This is the name of the page to be called:
       String pageName = "Hello.page";

       // First check if the servlet was invoked with a queryString that contains
    // a markup-language value.
       // For example, if this is how the  servlet is invoked:
       //  http://localhost/servlets/HeloPervasive?mlname=VXML
       //  then use the following method:
       String mlname= getMLNameFromRequest(request);

        // If no markup language type is provided in the queryString,
        // then try to determine the client
        // Type from the request, and use the markup-language name configured in
        // the client_types.xml file.
        if (mlName == null)
        {
          mlName = getMLTypeFromRequest(request);
         }
         try
         {
           // Serve the request page.
           callPage(mlName, pageName, request, response);
          }
          catch (Exception e)
          {
```

```
            handleError(mlName, request, response, e);
           }
       }
}
```

*Page lists:*

Page lists allow you to avoid hard-coding Uniform Resource Locators (URLs) in servlets and JSP files. A page list specifies the location where a request is to be forwarded, but automatically customizes that location depending on the MIME type of the servlet. Use these properties to specify a markup language and an associated MIME type. For the given MIME type, you also specify a set of pages to invoke.

**Note:** The PageList Servlet custom extension is deprecated in WebSphere Application Server Version 8.0 and will be removed in a future release. Re-architect your legacy applications to use javax.servlet.filter classes instead of com.ibm.servlet classes. Starting from the Servlet 2.3 specification, javax.servlet.filter classes you can intercept requests and examine responses. You can also use javax.servlet.filter classes to achieve chaining functionality, as well as embellishing or truncating responses.

The following list of classes are deprecated:

- com.ibm.servlet.ClientList
- com.ibm.servlet.ClientListElement
- com.ibm.servlet.MLNotFoundException
- com.ibm.servlet.PageListServlet
- com.ibm.servlet.PageNotFoundException

WebSphere Application Server supplies the PageListServlet servlet, which you can use to call a JavaServer Pages (JSP) file by name based on the configuration data in the `client_types.xml` file. This file maps a JSP file to a Uniform Resource Identifier (URI). When the URI is invoked, it specifies another JSP file in a web module. This support allows you to access multiple URLs without hard-coding them in your servlets.

You can also logically group page lists according to the markup language type, such as, Hypertext Markup Language (HTML) or Wireless Markup Language (WML). This allows applications that use servlets to extend the PageListServlet servlet, to call JSP files which return the proper markup-language type for the client request. For example, a request that originates from a PDA device requires WML data. The application server sends the request to a servlet that extends the PageListServlet servlet, and the servlet calls a JSP file that returns a WML response.

*Client type detection support:*

In addition to providing the page list mapping capability, the PageListServlet also provides *Client Type Detection* support. A servlet determines the markup language type that a calling client needs in the response, using the configuration information in the `client_types.xml` file.

Client type detection support allows a servlet, extending the PageListServlet, to call an appropriate JavaServer Pages (JSP) file. The servlet invokes the `callPage` method, which calls a JSP file based on the markup-language type of the request.

The PageList Servlet custom extension is deprecated in WebSphere Application Server Version 8.0 and will be removed in a future release. Re-architect your legacy applications to use javax.servlet.filter classes instead of com.ibm.servlet classes.

*client_types.xml:*

The client_types.xml file provides client type detection support for servlets extending PageListServlet. Using the configuration data in the client_types.xml file, servlets can determine the language type that calling clients require for the response.

**Attention:** The PageList Servlet custom extension is deprecated in WebSphere Application Server Version 8.0 and will be removed in a future release. Re-architect your legacy applications to use javax.servlet.filter classes instead of com.ibm.servlet classes.

The client type detection support allows servlets to call appropriate JavaServer Pages (JSP) files with the callPage method. Servlets select JSP files based on the markup-language type of the request.

Servlets must use the following version of the callPage method to determine the markup language type required by the client:

```
callPage(String mlName, String pageName, HttpServletRequest request,
                  HttpServletResponse response)
```

where the arguments are:
- mlName - a markup language type
- pageName - a page name defined in the PageListServlet configuration
- request - the HttpServletRequest object
- response - the HttpServletResponse object

Review the Extending the PageListServlet code example in the Extending the PageListServlet topic, to see how the callPage method is invoked by a servlet.

In the example, the client type detection method, getMLTypeFromRequest(HttpServletRequestrequest), provided by the PageListServlet, inspects the HttpServletRequest object request headers, and searches for a match in the client_types.xml file.

The client type detection method does the following:
- Uses the input HttpServletRequest and the client_types.xml file, to check for a matching HTTP request name and value.
- Returns the markup-language value configured for the <client-type> element, if a match is found.
- If multiple matches are found, this method returns the markup-language for the first <client-type> element for which a match is found.
- If no match is found, returns the value of the markup-language for the default page defined in the PageListServlet configuration.

**Location**

The client_types.xml file is located in the *install_root*/properties directory.

**Usage notes**
- Is this file read-only?

  No
- Is this file updated by a product component?

  No
- If so, what triggers its update?

  This file is created and updated manually by users.
- How and when are the contents of this file used?

  Servlets that extending the PageListServlet servlet use this file to determine the language type that calling clients require for the response.

### Sample file entry

```
<?xml version="1.0" >
<!DOCTYPE clients [
<!ELEMENT client-type (description, markup-language,request-header+)>
<!ELEMENT description (#PCDATA)>
<!ELEMENT markup-language (#PCDATA)>
<!ELEMENT request-header (name, value)>
<!ELEMENT clients (client-type+)>
<!ELEMENT name (#PCDATA)>
<!ELEMENT value (#PCDATA)>]>
<clients>
      <client-type>
      <description>IBM Speech Client</description>
      <markup-language>VXML</markup-language>
      <request-header>
           <name>user-agent</name>
           <value>IBM VoiceXML pre-release version 000303</value>
      </request-header>
      <request-header>
           <name>accept</name>
           <value>text/vxml</value>
      </request-header>
      </client-type>
      <client-type>
           <description>WML Browser</description>
           <markup-language>WML</markup-language>
      <request-header>
           <name>accept</name>
           <value>text/x-wap.wml</value>
      </request-header>
      <request-header>
           <name>accept</name>
           <value>text/vnd.wap.xml</value>
      </request-header>
    </client-type>
</clients>
```

***client_types.xml:***

The `client_types.xml` file provides client type detection support for servlets extending PageListServlet. Using the configuration data in the `client_types.xml` file, servlets can determine the language type that calling clients require for the response.

**Attention:** The PageList Servlet custom extension is deprecated in WebSphere Application Server Version 8.0 and will be removed in a future release. Re-architect your legacy applications to use javax.servlet.filter classes instead of com.ibm.servlet classes.

The client type detection support allows servlets to call appropriate JavaServer Pages (JSP) files with the `callPage` method. Servlets select JSP files based on the markup-language type of the request.

Servlets must use the following version of the `callPage` method to determine the markup language type required by the client:

```
callPage(String mlName, String pageName, HttpServletRequest request,
                  HttpServletResponse response)
```

where the arguments are:
- mlName - a markup language type
- pageName - a page name defined in the PageListServlet configuration
- request - the HttpServletRequest object
- response - the HttpServletResponse object

Review the Extending the PageListServlet code example in the Extending the PageListServlet topic, to see how the `callPage` method is invoked by a servlet.

In the example, the client type detection method, `getMLTypeFromRequest(HttpServletRequestrequest)`, provided by the PageListServlet, inspects the HttpServletRequest object request headers, and searches for a match in the `client_types.xml` file.

The client type detection method does the following:
- Uses the input HttpServletRequest and the `client_types.xml` file, to check for a matching HTTP request name and value.
- Returns the markup-language value configured for the `<client-type>` element, if a match is found.
- If multiple matches are found, this method returns the markup-language for the first `<client-type>` element for which a match is found.
- If no match is found, returns the value of the markup-language for the default page defined in the PageListServlet configuration.

### Location

The `client_types.xml` file is located in the *install_root*`/properties` directory.

### Usage notes
- Is this file read-only?

  No
- Is this file updated by a product component?

  No
- If so, what triggers its update?

  This file is created and updated manually by users.
- How and when are the contents of this file used?

  Servlets that extending the PageListServlet servlet use this file to determine the language type that calling clients require for the response.

### Sample file entry

```
<?xml version="1.0" >
<!DOCTYPE clients [
<!ELEMENT client-type (description, markup-language,request-header+)>
<!ELEMENT description (#PCDATA)>
<!ELEMENT markup-language (#PCDATA)>
<!ELEMENT request-header (name, value)>
<!ELEMENT clients (client-type+)>
<!ELEMENT name (#PCDATA)>
<!ELEMENT value (#PCDATA)>]>
<clients>
      <client-type>
      <description>IBM Speech Client</description>
      <markup-language>VXML</markup-language>
      <request-header>
           <name>user-agent</name>
           <value>IBM VoiceXML pre-release version 000303</value>
      </request-header>
      <request-header>
           <name>accept</name>
           <value>text/vxml</value>
      </request-header>
      </client-type>
      <client-type>
           <description>WML Browser</description>
           <markup-language>WML</markup-language>
      <request-header>
           <name>accept</name>
```

```
            <value>text/x-wap.wml</value>
        </request-header>
        <request-header>
            <name>accept</name>
            <value>text/vnd.wap.xml</value>
        </request-header>
    </client-type>
</clients>
```

***Java Servlet 3.0 considerations:***

When using Servlet 3.0 web modules, keep in mind the following features.

**Note:** Java Servlet 3.0 has many, new powerful features. Some of these features are not fully documented in the Servlet 3.0 specification or they entail trade-offs. Consider the following topics to make best use of the new features.

**Annotations**

**Note:**

Java Servlet 3.0 annotations are picked up in Servlet 2.5 web modules, which can include exposing a servlet on the web. Use caution when upgrading prerequisites of an older application, because the new annotations are processed and the prerequisites JAR file might include annotations that you do not want applied.

**File upload**

When using the file upload (multipart forms) support that is new to Servlet 3.0, the default location for writing files is the same as the value of the javax.servlet.context.tempdir servlet context attribute. For example, `C:\opt\WAS\profiles\node1\temp\node1\server1\fragmentTest\fragmentTest24.war` is produced for a configuration with the following attributes:

- profile home=C:\opt\WAS\profiles\node1
- server name=server1
- enterprise application name=fragmentTest
- web module name=fragmentTest24.war

Relative paths are also relative to this default location.

You can change the value of the javax.servlet.context.tempdir servlet context attribute to be relative to a different directory by setting the com.ibm.websphere.servlet.temp.dir system property. This system property affects all applications on a server-wide basis. For example, if you set com.ibm.websphere.servlet.temp.dir to `/foo`, the application temp directory is `/foo/node1/server1/fragmentTest/fragmentTest24.war`. If you want to change the value at an application level, use the scratchdir JavaServer Pages (JSP) attribute. View the JSP engine configuration parameters topic for more information about the scratchdir attribute.

**Programmatic or dynamic HTTP session configuration**

Programmatic HTTP session configuration enables an application to modify the session configuration in use, either through `web.xml` file configuration or through API method calls. After the application starts, a dynamically modified cookie name cannot be changed. For security purposes, administrators can disable programmatic session configuration for particular cookies that can be shared between applications. Generally, it is safe to modify the cookie configuration, if the application uses a unique cookie name or path. You can change the default cookie path for each application to use the context root through the session management.

**Important:** Changing the path can affect certain IBM extensions, such as session sharing or the IBMSessionExt.invalidateAll method that rely on using one cookie for multiple applications.

***Servlet 3.0 programmatic configuration:***

The configuration methods, addListener, addFilter, and addServlet are introduced in the Servlet 3.0 specification.

**Note:** The new methods for Servlet 3.0 are part of the ServletContext interface. You can call these methods from either a ServletContainerInitializer or a ServletContextListener.

**addListener**

The addGlobalListener method is deprecated in WebSphere Application Server Version 8.0. It is replaced with the addListener method.

- Use the following method to add the listener with the given class name to this servlet context:
  `void addListener(java.lang.String className)`
- Use the following method to add the given listener to this servlet context:
  `<T extends java.util.EventListener> void addListener(T t)`
- Use the following method to add a listener of the given class type to this servlet context:
  `void addListener(java.lang.Class<? extends java.util.EventListener> listenerClass)`

The given listener class must implement one or more of the following interfaces:

- ServletContextAttributeListener
- ServletRequestListener
- ServletRequestAttributeListener
- HttpSessionListener
- HttpSessionAttributeListener

**addFilter**

The addMappingFilter method is deprecated in WebSphere Application Server Version 8.0. It is replaced with the addFilter method. This method adds the filter with the given name, description, and class name to the Web application context. The registered filter might be further configured using the returned FilterRegistration object.

- Use the following method to add the filter with the given name and class type to this servlet context:
  `addFilter(java.lang.String filterName, java.lang.Class<? extends Filter> filterClass)`
- Use the following method to register the given filter instance with this servlet context under the given filterName:
  `addFilter(java.lang.String filterName, Filter filter)`
- Use the following method to add the filter with the given name and class name to this servlet context:
  `addFilter(java.lang.String filterName, java.lang.String className)`

**addServlet**

The addServlet methods dynamically adds servlets to a servletContext. These methods will add the servlet with the given parameters to the web application context. The registered servlet might be further configured using the returned ServletRegistration object.

- Use the following method to add the filter with the given name and class type to this servlet context:
  `addFilter(java.lang.String filterName, java.lang.Class<? extends Filter> filterClass)`
- Use the following method to register the given filter instance with this servlet context under the given filterName:

`addFilter(java.lang.String filterName, Filter filter)`

- Use the following method to add the filter with the given name and class name to this servlet context:
  `addFilter(java.lang.String filterName, java.lang.String className)`

**ServletContainerInitializer**

When you configure a JAR file for a shared library and a ServletContainerInitializer is discovered within the JAR, the ServletContainerInitializer is invoked for every application that the shared library associates with.

**Deprecated classes in Servlet 3.0**

The following classes are deprecated from com.ibm.websphere.servlet.context.IBMServletContext:

- public void addDynamicServlet(String servletName, String servletClass, String mappingURI, Properties initParameters) throws ServletException, java.lang.SecurityException;
- public void removeDynamicServlet(String servletName) throws java.lang.SecurityException

There is no replacement for the removeDynamicServlet method because removing a servlet can lead to timing issues if a request was servicing that servlet at the same time. The addServlet and createServlet methods replace the addDynamicServlet method.

***Initial parameters for servlets settings:***

Use this page to specify initial parameters that are passed to the init method of web module servlet filters. You can specify initial parameter values for servlets in web modules during or after installation of an application onto a WebSphere Application Server deployment target. The `<param-value>` values specified in `<init-param>` statements in the `web.xml` file of web modules are used by default.

To view this administrative console page, click **Applications** > **Application Types** > **WebSphere enterprise applications** > ***application_name*** > **Init parameters for servlets**. This page is the same as the Init parameters for servlets in each web module panel on the application installation and update wizards.

*Module:*

Specifies the name of a module in the application that you are installing or that you are viewing after installation.

*URI:*

Specifies the location of the module relative to the root of the application (EAR file).

*Servlet:*

Specifies a unique name for the servlet within the application.

A *servlet* is a Java program that uses the Java Servlet Application Programming Interface (API). You must package servlets in a Web archive (WAR) file or web module for deployment to an application server. Servlets run on a Java-enabled web server and extend the capabilities of a web server, similar to the way applets run on a browser and extend the capabilities of a browser.

*Name:*

Specifies the name of the initial parameter passed to the init method of the web module servlet filter.

The following example servlet filter statement in a `web.xml` file specifies an initial parameter name of `attribute`:

```
<init-param>
   <param-name>attribute</param-name>
   <param-value>tests.Filter.DoFilter_Filter.SERVLET_MAPPED</param-value>
</init-param>
```

*Value:*

Specifies the value assigned to an initial parameter passed to the init method of the web module servlet filter.

The following example servlet filter statement in a `web.xml` file specifies an initial parameter value of `tests.Filter.DoFilter_Filter.SERVLET_MAPPED` for the init parameter `attribute`:

```
<init-param>
   <param-name>attribute</param-name>
   <param-value>tests.Filter.DoFilter_Filter.SERVLET_MAPPED</param-value>
</init-param>
```

*Description:*

Specifies information on the initial parameter.

***Servlet filtering:***

*Servlet filtering* provides a new type of object called a *filter* that can transform a request or modify a response.

You can chain filters together so that a group of filters can act on the input and output of a specified resource or group of resources.

Filters typically include logging filters, image conversion filters, encryption filters, and Multipurpose Internet Mail Extensions (MIME) type filters (functionally equivalent to the servlet chaining). Although filters are not servlets, their life cycle is very similar.

Filters are handled in the following manner:

1. The web container determines whether it needs to construct a `FilterChain` containing the `LoggingFilter` for the requested resource.

   The `FilterChain` begins with the invocation of the `LoggingFilter` and ends with the invocation of the requested resource.
2. If other filters need to go in the chain, the web container places them after the`LoggingFilter` and before the requested resource.
3. The web container then instantiates and initializes the `LoggingFilter` (if it was not done previously) and invokes its `doFilter(FilterConfig)` method to start the chain.
4. The `LoggingFilter` preprocesses the request and response objects and then invokes the filter chain `doFilter(ServletRequest, ServletResponse)` method.

   This method passes the processing to the next resource in the chain, the requested resource.
5. Upon return from the filter chain `doFilter(ServletRequest, ServletResponse)` method, the `LoggingFilter` performs post-processing on the request and response object before sending the response back to the client.

Java Servlet Specification 2.4 enables you to define a new `<dispatcher>` element in the deployment descriptor with possible values such as REQUEST, FORWARD, INCLUDE, ERROR, instead of invoking filters with RequestDispatcher.

Java Servlet Specification 3.0 enables you to define a new <dispatcher> element in the deployment descriptor with possible values such as ASYNC, REQUEST, FORWARD, INCLUDE, ERROR, instead of invoking filters with RequestDispatcher.

For example:

```
<filter-mapping>
<filter-name>Logging Filter</filter-name>
<url-pattern>/products/*</url-pattern>
<dispatcher>FORWARD</dispatcher>
<dispatcher>REQUEST</dispatcher>
</filter-mapping>
```

This indicates that the filter should be applied to requests directly from the client as well as forward requests. Adding the INCLUDE and ERROR values also indicates that the filter should additionally be applied for included requests and <error-page> requests. If you do not specify any <dispatcher> elements, then the default is REQUEST.

**Filter, FilterChain, FilterConfig classes for servlet filtering**

The following interfaces are defined as part of the javax.servlet package:
- Filter interface - methods: doFilter, getFilterConfig, setFilterConfig
- FilterChain interface - methods: doFilter
- FilterConfig interface - methods: getFilterName, getInitParameter, getInitParameterNames, getServletContext

The following classes are defined as part of the javax.servlet.http package:
- HttpServletRequestWrapper - methods: See the Servlet 2.4 Specification
- HttpServletResponseWrapper - methods: See the Servlet 2.4 Specification

***autoRequestEncoding and autoResponseEncoding:***

Starting with WebSphere Application Server Version 5, the web container no longer automatically sets request and response encodings, and response content types. Programmers are expected to set these values using available methods in the Servlet 2.3 specification or later. If programmers choose not to use the character encoding methods, they can specify the `autoRequestEncoding` and `autoResponseEncoding` extensions, which enable the application server to set the encoding values and content type.

The values of the `autoRequestEncoding` and `autoResponseEncoding` extensions are either `true` or `false`. The default value for both extensions is `false`. If the value is `false` for both `autoRequestEncoding` and `autoResponseEncoding`, then the request and response character encoding is set to the Servlet Specification default, which is ISO-8859-1. Also, if the value is set to `false` for a response, the web container cannot set a response content type. Different character encodings are possible if the client defines character encoding in the request header, or if the code includes the `setCharacterEncoding(String encoding)` method.

If the `autoRequestEncoding` value is set to `true`, and the client did not specify character encoding in the request header, and the code does not include the `setCharacterEncoding(String encoding)` method, the web container tries to determine the correct character encoding for the request parameters and data.

Use an assembly tool to change the default values for the `autoRequestEncoding` and `autoResponseEncoding` extensions.

The web container performs each step in the following list until a match is found:
- Looks at the character set (charset) in the *Content-Type* header.
- Attempts to map the servers locale to a character set using defined properties.
- Attempts to use the `DEFAULT_CLIENT_ENCODING` system property, if one is set.
- Uses the ISO-8859-1 character encoding as the default.

If the `autoResponseEncoding` value is set to `true`, and the client did not specify character encoding in the request header, and the code does not include the `setCharacterEncoding(String encoding)` method, the web container does the following:
- Attempts to determine the response content type and character encoding from information in the request header.
- Uses the ISO-8859-1 character encoding as the default.

***Application life cycle listeners and events:***

With application life cycle listeners and events, which are now part of the Servlet API, you can notify interested listeners when servlet contexts and sessions change. For example, you can notify users when attributes change and if sessions or servlet contexts are created or destroyed.

The life cycle listeners give the application developer greater control over interactions with ServletContext and HttpSession objects. Servlet context listeners manage resources at an application level. Session listeners manage resources that are associated with a series of requests from a single client. Listeners are available for life cycle events and for attribute modification events. The listener developer creates a class that implements the javax listener interface, corresponding to the listener functionality that you want.

At application startup time, the container uses *introspection* to create an instance of your listener class and registers it with the appropriate event generator.

When a servlet context is created, the contextInitialized method of your listener class is invoked, which creates the database connection for the servlets in your application to use if this context is for your application. All servlet context listeners are notified of context initialization before any servlet in the web application is initialized.

When the servlet context is destroyed, your contextDestroyed method is invoked, which releases the database connection, if this context is for your application. You must destroy all servlets before any servlet context listeners are notified of context destruction.

Notifications to session listeners precede notifications to context listeners.

**Listener classes for servlet context and session changes**

The following methods are defined as part of the javax.servlet.ServletContextListener interface:
- void contextInitialized(ServletContextEvent)

  Notification that the web application is ready to process requests. Place code in this method to see if the created context is for your web application and if it is, allocate a database connection and store the connection in the servlet context.
- void contextDestroyed(ServletContextEvent)

  Notification that the servlet context is about to shut down. Place code in this method to see if the created context is for your web application and if it is, close the database connection stored in the servlet context.

The following methods are defined as part of the `javax.servlet.ServletRequestListener` interface:
- `public void requestInitialized(ServletRequestEvent re)`
  - Notification that the request is about to come into scope

    A request is defined as coming into scope when it is about to enter the first filter in the filter chain that processes the request.
- `public void requestDestroyed(ServletRequestEvent re)`
  - Notification that the request is about to go out of scope

    A request is defined as going out of scope when it exits the last filter in its filter chain.

The following listener interfaces are defined as part of the javax.servlet package:

- ServletContextListener
- ServletContextAttributeListener

The following filter interface is defined as part of the javax.servlet package:
- FilterChain interface - methods: doFilter()

The following event classes are defined as part of the javax.servlet package:
- ServletContextEvent
- ServletContextAttributeEvent

The following interfaces are defined as part of the javax.servlet.http package:
- HttpSessionListener
- HttpSessionAttributeListener
- HttpSessionActivationListener

The following event class is defined as part of the javax.servlet.http package:
- HttpSessionEvent

**Example: Creating a servlet context listener with com.ibm.websphere.DBConnectionListener.java**

The following example shows how to create a servlet context listener:

```
package com.ibm.websphere;

import java.io.*;
import javax.servlet.*;

public class DBConnectionListener implements ServletContextListener
{
     // implement the required context init method
    void contextInitialized(ServletContextEvent sce)
    {
    }

     // implement the required context destroy method
    void contextDestroyed(ServletContextEvent sce)
    {
    }
}
```

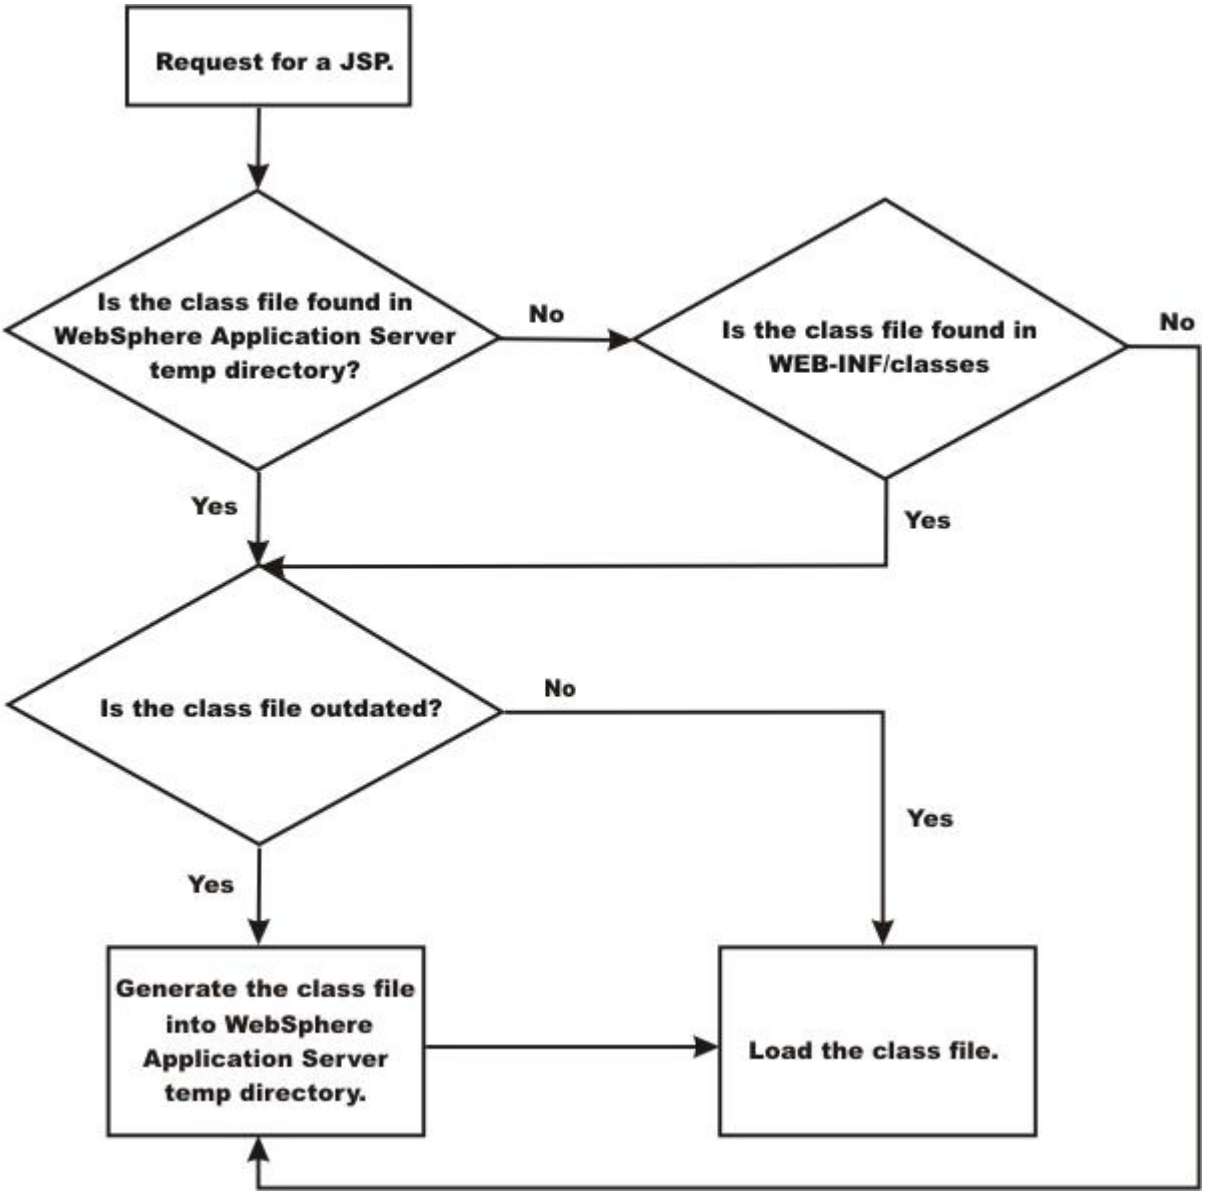
# Developing JSP files

Learn about JSP files.

## JSP class file generation

At runtime, the WebSphere Application Server JavaServer Pages (JSP) engine loads JSP class files from either the WebSphere Application Server `temp` directory or a web module's `WEB-INF/classes` directory. The JSP engine first searches for a class file in the `temp` directory and then it searches in the web module's `WEB-INF/classes` directory.

In a default installation, the WebSphere Application Server `temp` directory is typically *`profile_root`*`/temp`. Figure 1 shows the processing logic of the JSP engine at runtime.



The batch compiler supports the generation of class files in both the WebSphere Application Server `temp` directory and a web module's `WEB-INF/classes` directory, depending on the type of batch compiler target. In addition, the batch compiler enables the generation of class files into any directory on the filesystem, outside of the target application. Generating class files into a web module's `WEB-INF/classes` directory enables you to deploy the web module as a self-contained web application archive (WAR) file, or a WAR file inside an enterprise archive (EAR) file. The following table shows the batch compiler's behavior when compiling class files.

*Table 164. Batch compiler behavior. Batch compiler behavior when compiling class files*

| | ear.path or war.path supplied | enterpriseApp.name supplied |
|---|---|---|
| *compileToDir* not supplied; *compileToWebInf* not supplied, or is true | The class files are compiled into the web module's `WEB-INF/classes` directory. | The class files are compiled into the web module's `WEB-INF/classes` directory. |
| *compileToDir* not supplied; *compileToWebInf* is false | The class files are compiled into the web module's `WEB-INF/classes` directory. | The class files are compiled into the WebSphere Application Server temp directory, usually *profile_root*`/temp`. |

*Table 164. Batch compiler behavior (continued). Batch compiler behavior when compiling class files*

| | | |
|---|---|---|
| *compileToDir* is supplied; *compileToWebInf* not supplied, or is either true or false | The class files are compiled into the directory indicated by *compileToDir*. | The class files are compiled into the directory indicated by *compileToDir*. |

## Web container configuration for JavaServer Pages static file access

The web container searches for static files and JavaServer Pages (JSP) files in up to four different locations, depending on application configuration. This search is relevant to finding the appropriate resource to serve an inbound request and for results returned from the following APIs:

```
URL ServletContext.getResource(String path)
Set ServletContext.getResourcePaths(String path)
```

**Attention:** Static files are only searched when the **fileServing** property is enabled and the application does not include a `/*` servlet mapping. Also, JSP files include files with the following extensions, in addition to any other patterns that are defined in the web.xml file

- .jsp
- .jspx
- .jsw
- .jsv

The four locations, in priority order, are as follows:

**Application WAR directory**

The web container first searches the application WAR directory for a requested resource. However, you cannot serve resources under the WEB-INF or META-INF directories for inbound requests, although they are accessible using the getResource() and getResourcePaths() methods.

**Pre-fragment document roots**

The web container searches any application defined pre-fragment document roots second. Define a pre-fragment document root in the `ibm-web-ext.xmi` file, located in the WEB-INF directory for the application. Define a pre-fragment document root for static files or JSP files, as follows:

```
Static files:
<fileServingAttributes xmi:id="<user-provided name>"
 name="preFragmentExtendedDocumentRoot"
 value="<user provided value>"/>
```

```
JSP files:
<jspAttributes xmi:id="<user provided name>" name="preFragmentExtendedDocumentRoot"
 value=<user provided value>"/>
```

The *<user provided name>* is a comma-separated list of directories that can include JAR or ZIP files from which static files or JSP files can be accessed. The list can be fully qualified or relative to the application ear directory. The attributes can be specified with identical values. Further, you can specify the same values by different applications.

**Note:** Pre-fragment document roots is a new function in WebSphere Application Server Version 8.0.

**META-INF/resources directories of fragments under the WEB-INF/Lib directory in the application WAR file**

After searching pre-fragment document roots, the web container searches web fragments. A web fragment comprises a JAR file in an application WEB-INF/lib directory. The JAR might include

static resources in a META-INF/resources directory that are defined within the JAR file. To prevent the web container from searching META-INF/resources directories, set the com.ibm.ws.webcontainer.SkipMetaInfResourcesProcessing web container custom property to `true`. The default value for the custom property is false.

```
com.ibm.ws.webcontainer.SkipMetaInfResourcesProcessing = true
```

**Note:** META-INF/resources directories of fragments under the WEB-INF/Lib directory in the application WAR file is a new function in WebSphere Application Server Version 8.0.

**Extended document roots**

Finally, the web container searches any application defined as extended document roots. Extended document roots were available in previous releases and are defined in the `ibm-web-ext.xmi` file, which is located in the application WEB-INF directory. Define extended document root for static files or JSP files, as follows:

```
Static files:
<fileServingAttributes xmi:id="<user provided name>" name="extendedDocumentRoot"
 value="<user provided value>"/>
```

```
JSP files:
<jspAttributes xmi:id="<user provided name>" name="extendedDocumentRoot"
 value=<user provide value>"/>
```

```
com.ibm.ws.webcontainer.SkipMetaInfResourcesProcessing = true
```

The *<user provided name>* is a comma-separated list of directories that can include JAR or ZIP files from which static files or JSP files can be accessed. The list can be fully qualified, or relative to the application EAR directory. You can specify both attributes with identical values. Also, different applications can specify the same values.

**Attention:** You might set the com.ibm.ws.webcontainer.ServeWelcomeFileFromExtendedDocumentRoot custom property to **true** to enable serving static welcome pages from a static file extended document root. The default value for the custom property is **false**.

```
com.ibm.ws.webcontainer.ServeWelcomeFileFromExtendedDocumentRoot = true
```

When the com.ibm.ws.webcontainer.ServeWelcomeFileFromExtendedDocumentRoot property is set to **true**, the web container searches in a static file extended document root for a static welcome file to serve for a request comprising a valid partial URL. For example, if a request specifies only the application context, and a welcome file is specified as index.html, the property must be set if index.html is to be served from a static file extended document.

```
com.ibm.ws.webcontainer.enablepartialurltoextendeddocumentroot = true
```

The default value is **false**.

If this property is set to **true**, the web container includes the contents of a static file extended document root when determining whether an inbound request is for a valid partial URL. For example, if a request specifies a URL that ends with /<application context>/<text> and <text> does not map to a servlet or static file, the web container considers this URL a valid partial URL only if <text> is a valid directory of the application. As a result if directory <text> exists only in a static file extended document root, this property must be set for the URI to be considered a valid partial URI.

**Important:** These properties are not required for static file pre-fragment document roots. Also, when determining a valid partial URL, the web container does not consider JSP pre-fragment and extended document roots.

## Packages and directories for generated .java and .class files

By default, the `.java` files for all JavaServer Pages (JSP) files are generated with the package statement, `package com.ibm._jsp;`. The JSP engine's class loader knows how to load JSP classes when they are all in the same package. The `.java` files are located in the filesystem within a directory structure mirroring the JSP source directory structure.

If the JSP engine configuration parameter **useFullPackageNames** is set to true, the `.java` files are generated with the package statement

```
Package _ibmjsp.<directory structure in which the jsp is located>;
```

The usage of full package names enables the configuration of a JSP as a servlet in the `web.xml` file. Refer to the JSP class loading settings topic for more information. The table below gives examples of packages and directory structures for generated `.java` and `.class` files.

*Table 165. Packages and directory structures for generated `.java` and `.class` files. Examples of packages and directory structures for generated `.java` and `.class` files.*

| | **Java package** | | **Location of `.java` or `.class` files in file system** | |
|---|---|---|---|---|
| **JSP file** | **default** | **useFullPackageNames=true** | **default** | **useFullPackageNames=true** |
| /myJsp.jsp | com.ibm._jsp | _ibmjsp | / | /_ibmjsp |
| /jspFiles/ jspOne.jsp | com.ibm._jsp | _ibmjsp.jspFiles | /jspFiles | /_ibmjsp/jspFiles |
| /dir with spaces/jspTwo.jsp | com.ibm._jsp | _ibmjsp.dir_20_with_20_spaces | /dir with spaces | /_ibmjsp/ dir_20_with_20_spaces |

### *Generated .java files:*

When the JSP engine's **keepgenerated** configuration parameter is set to true, the `.java` file that is generated for JavaServer Pages (JSP) is retained. The `.java` file contains information that is useful in debugging.

#### Dependency information

In the `.java` file, immediately following the class declaration, an array of dependent files is defined, if the source JSP has any dependencies. There are three types of files that are tracked as dependencies:

1. Files that are statically included in the JSP
2. Tag files that are used by the JSP, but only tag files that are not in Java Archive (JAR) files
3. TLD files that are used by the JSP, but only TLDs that are not in JAR files

This array is always generated, but the JSP engine uses it, in determining whether a JSP needs to be recompiled, only when the trackDependencies parameter is set to true.

In the example below, three JSP fragments, one TLD and one tag file are dependencies of the JSP jsp1.jsp. There are three parts to each array entry:

1. The path to the dependency, relative to the web module's context root. For example: `/dir1/frag1.jspf`
2. The long value representing the time the file was last modified. For example: 1082407108000
3. The String representation of the long value. For example: Mon Apr 19 16:38:28 EDT 2004

```
public final class _jsp1 extends com.ibm.ws.jsp.runtime.HttpJspBase
  implements com.ibm.ws.jsp.runtime.JspClassInformation {

  private static String[] _jspx_dependants;
  static {
  _jspx_dependants = new String[5];
  _jspx_dependants[0] = "/Banner.jspf^1082407108000^Mon Apr 19 16:38:28 EDT 2004";
  _jspx_dependants[1] = "/Footer.jspf^1077657462000^Tue Feb 24 16:17:42 EST 2004";
  _jspx_dependants[2] = "/dir1/frag1.jspf^1035396680000^Wed Oct 23 14:11:20 EDT 2002";
  _jspx_dependants[3] = "/utility.tld^1080069938000^Tue Mar 23 14:25:38 EST 2004";
  _jspx_dependants[4] = "/WEB-INF/tags/top.tag^1065440490000^Mon Oct 06 07:41:30 EDT 2003";
  }
```

### Version, JSP engine options, and WEB.XML information

The generated .java source contains a comment that lists information about the file which is located at the bottom of the generated file. This information includes:

- The date and time the `.java` file was generated
- The version, build number and build date of the WebSphere Application Server on which the `.java` file was generated
- The values of the JSP engine configuration parameters that were in effect when the file was generated
- The values of any `<jsp-config>` elements in the `web.xml` file that pertained to the source JSP file.

```
/*

```

## JSP batch compilation

As an IBM enhancement to JavaServer Pages (JSP) support, IBM WebSphere Application Server provides a batch JSP compiler that allows JSP page compilation before application deployment. The batch compiler validates the syntax of JSP pages, translates the JSP pages into Java source files, and compiles the Java source files into Java servlet class files. The batch compiler also validates tag files and generates their Java implementation classes.

Batch compilation of JSP pages in a predeployed application simplifies the deployment process and improves the runtime performance of JSP page by eliminating first-request compilations. The batch compiler also operates on enterprise applications that have been deployed into WebSphere Application Server.

The JSP batch compiler works on web modules that support Servlet 2.2 and later. The batch compiler works on JSP pages written to the JSP 2.1 specification or previous specifications back to JSP 1.0. It recognizes a Servlet 2.5 or later deployment descriptor, `web.xml`, and can use any jsp-config elements that it may contain. In a Servlet 2.3 (JSP 1.2) or Servlet 2.2 (JSP 1.1) deployment descriptor the batch compiler recognizes and uses any taglib elements that the descriptor may contain.

Batch compiling makes the first request for a JSP page much faster because the JSP page is already translated and compiled into a servlet. Batch compiling is also useful as a fast way to resynchronize all of the JSP pages for an application.

The batch compiler supports the generation of class files in both the WebSphere Application Server `temp` directory and a web module's `WEB-INF/classes` directory, depending on the type of batch compiler target. In addition, the batch compiler enables generation of class files into any directory on the filesystem, outside the target application. Generating class files into a web module's `WEB-INF/classes` directory enables the web module to be deployed as a self-contained WAR file, or a WAR inside an EAR.

Also, you can use shared libraries with the JSP batch complier. When you use the JSP batch compiler, you must either add the JAR to the WAR in the `<WEB-INF>/lib` directory, or add the JAR to the JVM class path to use shared libraries.

***JSPBatchCompiler command:***

The batch compiler validates the syntax of JavaServer Pages, translates the JSP pages into Java source files, and compiles the Java source files into Java Servlet class files. The batch compiler also validates tag files and generates their Java implementation classes. Use this function to batch compile your JSP files and thereby enable faster responses to the initial client requests for the JSP files on your production web server.

The batch compiler can be executed against compressed or expanded enterprise archive (EAR) files and web application archive (WAR) files, as well as enterprise applications and web modules that have been deployed into WebSphere Application Server. When the target is a deployed enterprise application, the server does not need to be running to execute the batch compiler. If the batch compiler is executed while the target sever is running, the server is not aware of an updated class file and does not load that class file unless the enterprise application is restarted. When the target is a compressed EAR file or WAR file, the batch compiler must expand it before executing.

### Processing of web modules

The batch compiler operates on one web module at a time. If the target is either an EAR file or an installed enterprise application that contains more than one web module, the batch compiler operates on each web module individually. This is done because JSP pages are configured on a web module basis, through the web module's web.xml deployment descriptor file. Within a web module, the batch compiler processes one directory at a time. It validates and translates each JSP page individually, and then invokes the Java compiler for the entire group of generated Java sources files in that directory. If one JSP page fails during the Java compilation phase, the Java compiler might not create class files for most or all of the JSP pages that successfully compiled in that directory.

### JSP file extensions

The batch compiler uses four things to determine what file extensions it should process:

1. Standard JSP file extensions
   - *.jsp
   - *.jspx
   - *.jsw
   - *.jsv
2. The url-pattern property of the jsp-property-group elements in the deployment descriptor file in Servlet 2.4 web modules
3. The **jsp.file.extensions** JSP engine configuration parameter (for pre-Servlet 2.4 web modules)
4. The batch compiler configuration parameter **jsp.file.extensions**

The standard extensions are always used by the batch compiler. If the web module contains a Servlet 2.4 deployment descriptor, the batch compiler also processes any url-patterns found within the jsp-config element. If the batch compiler target contains the JSP engine configuration parameter **jsp.file.extensions**, then those extensions are also processed. If the batch compiler configuration parameter **jsp.file.extensions** is present, the extensions given are also processed and will override the JSP engine configuration parameter **jsp.file.extensions**.

It is a good idea to give JSP 'fragments' an extension that is not processed by the batch compiler. Statically-included fragments that do not stand alone generate translation or compilation errors if processed. The JSP 2.0 Specification suggests that you use the extension `.jspf` for such files.

### Batch compiler command

Both a Windows batch file, `JspBatchCompiler.bat` and UNIX shell script `JspBatchCompiler.sh` for running the batch compiler from the command line are found in the `{WAS_ROOT}/bin` directory. An Ant task is also available for executing the batch compiler using Ant. See the topic, Batch Compiler Ant Task for additional information.

The batch compiler target is the only required parameter. The target is one of -ear.path, -war.path or -enterpriseapp.name.

```
JspBatchCompiler -ear.path | -war.path | -enterpriseapp.name <name>
   [-response.file <filename>]
   [-webmodule.name <name>]
   [-filename <jsp name | directory name>
   [-recurse <true | false>]
   [-config.root <path>]
   [-cell.name <name>]
   [-node.name <name>]
   [-server.name <name>]
   [-profileName <name>]
   [-extractToDir <path>]
   [-compileToDir <path>]
```

```
[-compileToWebInf <true | false>]
  [-compileToWebInf <true | false>]
  [-compileAfterFailure <true | false>]
[-translate <true | false>]
[-compile <true | false>]
[-removeTempDir <true | false>]
[-forceCompilation <true | false>]
[-useFullPackageNames <true | false>]
[-trackDependencies <true | false>]
[-createDebugClassfiles <true | false>]
[-keepgenerated <true | false>]
[-keepGeneratedclassfiles <true | false>]
[-usePageTagPool <true | false>]
[-useThreadTagPool <true | false>]
[-classloader.parentFirst <true | false>]
[-classloader.singleWarClassloader <true | false>]
[-additional.classpath <classpath to additional JAR files and classes>]

[-verbose <true | false>]
[-deprecation <true | false>]
[-javaEncoding <encoding>
[-jdkSourceLevel <13 | 14 | 15 | 16>]
[-compilerOptions <space-separated list of java compiler options>]
[-useJikes <true | false>]
[-jsp.file.extensions <file extensions to process>]
[-log.level <SEVERE | WARNING | INFO | CONFIG | FINE | FINER | FINEST | OFF>]
*** See batchcompiler.properties.default in WAS_ROOT/bin for more information. ***
*** See JspCBuild.xml in WAS_ROOT/bin for information about the public WebSphere Ant task JspC. ***
```

The batch compiler is aware of three groups of configuration parameters:

1. JSP engine configuration parameters for a web module.

   Refer to the JSP engine configuration parameters topic.
2. Batch compiler response file configuration parameters.

   These are the parameters that are found in a batch compiler response file. See -response.file, below.
3. Batch compiler command line configuration parameters.

   These are the parameters entered on the command line when running the batch compiler.

The batch compiler looks at all three groups of configuration parameters in order to determine which value for a parameter is used when compiling JSP pages. When resolving the value for a given parameter, the precedence is:

1. If the parameter is found on the command line, its value is used.
2. If the parameter is not found on the command line, the batch compiler looks for the parameter in a response file named on the command line.
3. If no response file is named, or if the parameter is not found therein, the batch compiler looks for the parameter in the web module's JSP engine configuration parameters.

If a configuration parameter is not found among these three groups, then a default value is used. The default values for the configuration parameters are given below along with the description of the parameters.

With one exception, these parameters are not case sensitive; -profileName is case sensitive. If the values specified for these arguments are comprised of two or more words separated by spaces, you must add quotation marks around the values.

The batch compiler does not create, or set the values of, equivalent JSP engine parameters. This means that if a JSP page in a deployed Web module is modified and is recompiled by the JSP engine at run time, the JSP engine's configuration parameters will determine the engine's behavior. For example, if you use the batch compiler to compile a web module and you use the -useFullPackageNames true option, the JSP

files will be compiled to support that option. But the JSP engine parameter useFullPackageNames must also be set to true in order for the JSP runtime to be able to load the compiled JSP pages. If JSP pages are modified in a deployed web module, then the engine's parameters should be set to the same values used in batch compilation.

To use the JSP batch compiler, enter one of the following commands on a single line at an operating system command prompt.:

- **ear.path | war.path | enterpriseapp.name**

  Represents the full path to a single compressed or expanded enterprise application archive (EAR) file or web application archive (WAR) file, or the name of the deployed enterprise application that you want to compile. For example:
  - `JspBatchCompiler -ear.path c:\myproject\sampleApp.ear`
  - `JspBatchCompiler -war.path c:\myWars\examples.war`
  - `JspBatchCompiler -enterpriseapp.name myEnterpriseApp -webmodule.name my.war -filename aDir/main.jsp`
- **response.file**

  Specifies the path to a file that contains configuration parameters used by the batch compiler. The *response.file* is used only if it is given on the command line; it is ignored if it is present in a response file.

  In a default installation, the template response file, batchcompiler.properties.default, is found in the `{WAS_ROOT}/bin` directory. Copy this template to create your own response files containing defaults for the parameters in which you are interested. All the required and optional parameters (except response.file) can be configured in a response file. **For example:** JspBatchCompiler -response.file c:\myproject\batchc.props

  **Default :** null
- **webmodule.name**

  Represents the name of the specific web module that you want to batch compile. If this argument is not set, all web modules in the enterprise application are compiled. This parameter is used only when *ear.path* or *enterpriseapp.name* is given. This parameter is useful when JSP pages in a specific web module within a deployed enterprise application need to be regenerated, because all shared library dependencies are picked up.

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -webmodule.name myWebModule.war

  **Default:** All web modules in an EAR file or enterprise application are compiled if this parameter is not given.
- **filename**

  Represents the name of a single JSP file that you want to compile. If this argument is not set, all files in the web module are compiled. Alternatively, if *filename* is set to the name of a directory, only the JSP files in that directory and that directory's child directories are complied. The name is relative to the context root of the web module.

  **Example 1:** If you want to compile the file, `myTest.jsp`, and it is found in `/subdir/myJSPs`, you would enter `-filename /subdir/myJSPs/myTest.jsp`.

  **Example 2:** If you want to compile all JSP files in `/subdir/myJSPs` and its child directories, you would enter `-filename subdir/myJSPs`.

  **Default:** All JSP files in the web module are compiled. Entering `-filename /` is equivalent to the default.
- **recurse**

  Determines whether subdirectories beneath the target directory are processed. This parameter is used only when the *filename* parameter is given. Set value to `false` to process only the directory named *filename* parameter; and not its subdirectories.

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -filename /subdir1 -recurse false.

  **Default:** true; All directories beneath the target directory are processed.
- **config.root**

Specifies the location of the WebSpehere Application Server configuration directory. This parameter is used only when *enterpriseapp.name* is given.

**Default:** `{WAS_ROOT}/profiles/profilename/config`

- **cell.name**

  Specifies the name of the cell in which the application is deployed. This parameter is used only when *enterpriseapp.name* is given.

  **Default:** The default is obtained from the profile script that is used. The symbolic name of this variable is WAS_CELL.

- **node.name**

  Specifies the name of the node in which the application is deployed. This parameter is used only when *enterpriseapp.name* is given.

  **Default:** The default is obtained from the profile script that is used. The symbolic name of this variable is WAS_NODE.

- **server.name**

  Represents the name of the server in which the application is deployed. This parameter is used only when *enterpriseapp.name* is given.

  **Default:** server1

- **profileName**

  Specifies the name of the profile you want to use. This parameter is used only when the *enterpriseapp.name* or *-ear.* path is given.

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -profileName AppServer-3

  **Default:** The default profile is used. This is obtained from the file `setupCmdLine` script in the *`install_root`*`/bin` directory. The symbolic name is DEFAULT_PROFILE_SCRIPT.

- **extractToDir**

  Specifies the directory into which predeployed enterprise archive (EAR) files and web application archive (WAR) files will be extracted before the batch compiler operates on them. This parameter is ignored when *enterpriseapp.name* is given. The extractToDir parameter is used as described in the table below.

  **Example:** JspBatchCompiler -ear.path c:\myproject\sampleApp.ear -extractToDir c:\myTempDir.

  **Use-case:** You must extract a compressed archive before it is batch compiled. You can also extract an expanded archive to a new directory as well. In both cases, extraction leaves the original archive untouched, which may be useful while development is underway.

*Table 166. extractToDir. Default values*

| | **Expanded archive** | **Compressed archive** |
|---|---|---|
| extractToDir supplied | The batch compiler extracts the archive to extractToDir before operating on it. If a file or directory of the same name as the archive already exists in the extractToDir, the batch compiler removes the archive completely before extracting that archive. If the batch compiler exits with no errors, it compresses the archive in place in the extractToDir, even if the original EAR file or WAR file was expanded. If errors are encountered during compilation, the EAR file or WAR file is left in the expanded state even if the original EAR file or WAR file was compressed. | |
| extractToDir not supplied | The batch compiler operates on the EAR file or WAR file in place (does not extract it to another directory) and the archive remains expanded after the batch compiler finishes. | The batch compiler extracts the archive to the directory returned by the JVM property "java.io.tmpdir". The rest of the behavior described above, when extractToDir is supplied, is the same in this case. |

The default is `server1`.

- **compileToDir**

Specifies the directory into which JSP pages are translated into Java source files and compiled into class files. This directory can be anywhere on the filesystem, but the batch compiler's default behavior is usually adequate. The batch compiler's behavior when compiling class files is described in the table below

**Example:**: JspBatchCompiler -enterpriseApp.name sampleApp -compileToDir c:\myTargetDir

**Use-case:** This parameter enables you to generate the Java and class files into a directory outside of the target, which may be useful if you want to compare the newly generated files with their previous versions which remain untouched within the target.

*Table 167. compileToDir. Default values*

| | **ear.path or war.path supplied** | enterpriseApp.name supplied |
|---|---|---|
| compileToDir not supplied; compileToWebInf not supplied, or is true | The class files are compiled into the web module's `WEB-INF/classes` directory | The class files are compiled into the web module's `WEB-INF/classes` directory. |
| compileToDir not supplied; compileToWebInf is false | The class files are compiled into the web module's `WEB-INF/classes` directory. | The class files are compiled into the WebSphere Application Server temp directory (usually `{WAS_ROOT}/temp`). |
| compileToDir is supplied; compileToWebInf not supplied, or is either true or false | The class files are compiled into the directory indicated by compileToDir. | The class files are compiled into the directory indicated by compileToDir. |

- **compileToWebInf**

  Specifies whether the target directory for the compiled JSP class files should be the web module's `WEB-INF/classes directory`. This parameter is used only when *enterpriseApp.name* is given, and it is overridden by *compileToDir* if *compileToDir* is given.

  The batch compiler's default behavior is to compile to the web module's `WEB-INF/classes` directory. The batch compiler's behavior when compiling class files is described in the table above.

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -compileToWebInf false.

  **Use-case:** Set this parameter to false when enterpriseApp.name is supplied and you want the class files to be compiled to the WebSphere Application Server temp directory instead of the web module's `WEB-INF/classes` directory. Recommendation: if this parameter is set to false, set forceCompilation to true if there are any JSP class files in the `WEB-INF/classes` directory.

  **Default:** true; see the table above.
- **compileAfterFailure**

  Specifies whether the JDK JSP batch compiler continues to compile the other JavaServer Pages (JSP) files in the current directory if one or more of the JavaServer Pages (JSP) files in that directory cannot be complied. Typically when one of the files cannot be compiled, the JSP batch complier skips all of the remaining JSPs in that directory, and starts to compile the files in the next directory.

  If you set this parameter to true, you must also specify the useJDKCompiler parameter and set that parameter to true.

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -useJDKCompiler true –compileAfterFailure false.

  **Use-case:** Set this parameter to true if you want the JSP batch compiler compile the other JavaServer Pages (JSP) files in the current directory even if one or more of the JSP files in that directory cannot be complied.

  **Default:** false
- **forceCompilation**

  Specifies whether the batch compiler is forced to recompile all JSP resources regardless or whether the JSP page is outdated.

  **Example**: JspBatchCompiler -ear.path c:\myproject\sampleApp.ear -forceCompilation true.

  **Use-case:** Especially useful when creating an archive for deployment, to make sure all JSP classes are up to date.

**Default:** false

- **useFullPackageNames**

  Specifies whether the batch compiler generates full package names for JSP classes. The default is to generate all JSP classes in the same package. The JSP engine's class loader knows how to load JSP classes when they are all in the same package. The default has the benefit of generating smaller file-system paths. Full package names have the benefit of enabling the configuration of precompiled JSP class files as servlets in the `web.xml` file without use of the `jsp-file` attribute, resulting in a single class loader (the web application's class loader) being used to load all such JSP classes. Similarly, when the JSP engine's configuration attributes **useFullPackageNames** and **disableJspRuntimeCompilation** are both true, a single class loader is used to load all JSP classes, even if the JSP pages are not configured as servlets in the `web.xml` file.

  When useFullPackageNames is set to true, the batch compiler generates a file called `generated_web.xml` in the web module's `WEB-INF` directory. This file contains servlet configuration information for each JSP page that is successfully translated and compiled. The information can optionally be copied into the web module's `web.xml` file so that the JSP pages are loaded as servlets by the web container. Note that if a JSP page is configured as a servlet in this way, no reloading of the JSP page is done at run time if the JSP page is modified. This is because the JSP page is treated as a regular servlet and requests for it do not pass through the JSP engine.

  **Example:** JspBatchCompiler –enterpriseApp.name sampleApp –useFullPackageNames true

  **Use-case:** Enables JSP classes to be loaded by a single class loader.

  **Default:** false

- **removeTempDir**

  Specifies whether the web module's temp directory is removed. The batch compiler by default generates JSP class files into a web module's `WEB-INF/classes` directory. JSP class files are generated into the `temp` directory at run time if a JSP page is modified and JSP reloading is enabled. By batch compiling all the JSP pages in a web module and also removing the `temp` directory, disk resources are preserved. You can only use the removeTempDir parameter when -enterpriseApp.name is given.

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -removeTempDir true.

  **Use-case:** Free up disk space by clearing out a web application's `temp` directory.

  **Default:** false

- **translate**

  Specifies whether JSP pages are translated and compiled. Set translate to false if you do not want JSP pages to be translated and compiled. You must use this option in conjunction with `-removeTempDir` to tell the batch compiler to remove only the `temp` directory and to do no further processing.

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -translate false -removeTempDir true.

  **Use-case:** Free up disk space by clearing out a web application's `temp` directory, without invoking JSP processing.

  **Default:** true

- **compile**

  Specifies whether JSP pages go through the Java compilation phase. Set compile to `false` if you do not want JSP pages to go through the Java compilation phase.

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -compile false

  **Use-case:** If you only want JSP pages to be syntax-checked, set -compile to false. You can set -keepgenerated to true if you want to see the `.java` files that are generated during the translation phase.

  **Default:** true

- **trackDependencies**

  Specifies whether the batch compiler recompiles a JSP page when any of its dependencies have changed, even if the JSP page itself has not changed. Tracking dependencies incurs a significant

runtime performance penalty because the JSP Engine checks the filesystem on every request to a JSP page to see if any of its dependencies have changed. The dependencies tracked by WebSphere Application Server are :

1. Files statically included in the JSP page
2. Tag files used by the JSP page (excluding tag files that are in JAR files)
3. TLD files used by the JSP page (excluding TLD files that are in JAR files)

**Example:** JspBatchCompiler -ear.path c:\myproject\sampleApp.ear -trackDependencies true.

**Use-case:** Useful in a development environment.

**Default:** false

- **createDebugClassfiles**

  Specifies whether the batch compiler generates class files that contain SMAP information, as per JSR 45, **Debugging support for Other Languages**.

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -createDebugClassfiles true

  **Use-case:** Use this parameter when you want to be able to debug JSP pages in your JSR 45-compliant IDE.

  **Default:** false
- **keepgenerated**

  Specifies whether the batch compiler saves or erases the generated Java source files created during the translation phase.

  If set to `true`, WebSphere Application Server saves the generated `.java` files used for compilation on your server. By default, this argument is set to `false` and the `.java` files are erased after the class files have compiled.

  **Example:** JspBatchCompiler -ear.path c:\myproject\sampleApp.ear -keepgenerated true

  **Use-case:** Use this parameter when you want to review the Java code generated by the batch compiler.

  **Default:** false
- **keepGeneratedclassfiles**

  Specifies whether the batch compiler saves or erases the class files generated during the compilation of Java source files.

  **Example:** JspBatchCompiler -ear.path c:\myproject\sampleApp.ear -keepGeneratedclassfiles false -keepgenerated false

  **Use-case:** Set this parameter to false if you only want to see if there are any translation or compilation errors in your JSP pages. If paired with -keepgenerated false, this parameter results in all generated files being removed before the batch compiler completes.

  **Default:** true
- **usePageTagPool**

  Enables or disables the reuse of custom tag handlers on an individual JSP page basis.

  **Example:** JspBatchCompiler -ear.path c:\myproject\sampleApp.ear -usePageTagPool true

  **Use-case:** Use this parameter to enable JSP-page-based reuse of tag handlers.

  **Default:** false
- **useThreadTagPool**

  Enables or disables the reuse of custom tag handlers on a per request thread basis per web module.

  **Example:** JspBatchCompiler -ear.path c:\myproject\sampleApp.ear -useThreadTagPool true

  **Use-case:** Use this parameter to enable web module-based reuse of tag handlers.

  **Default:** false
- **classloader.parentFirst**

  Specifies the search order for loading classes by instructing the batch compiler to search the parent class loader prior to application class loader. This parameter is only used when *ear.path* or *enterpriseApp.name* is given.

  **Example:** JspBatchCompiler -ear.path c:\myproject\sampleApp.ear -classloader.parentFirst false

**Use-case**: Set this parameter to false when your web module contains a JAR file that is also found in the server lib directory, and you want your web module's JAR file to be picked up first.

**Default:** true

- **classloader.singleWarClassloader**

  Specifies whether to use one class loader per enterprise archive (EAR) file or one class loader per web application archive (WAR) file. Used only when *ear.path* or *enterpriseApp.name* is given.

  **Example:** JspBatchCompiler -ear.path c:\myproject\sampleApp.ear -classloader.singleWarClassloader true

  **Use-case**: Set this parameter to true when a Web module depends on JAR files and classes in another web module in the same enterprise application.

  **Default:** false; One class loader is created per WAR file with no visibility of classes in other web modules.

- **additional.classpath**

  Specifies additional class path entries to be used when parsing and compiling JSP pages. This parameter is used only when `war.path` is given. When `war.path` is the target, WebSphere Shared Libraries are not picked up by the batch compiler. Therefore, if your WAR file relies on, for example, a JAR file that is configured in WebSphere Application Server as a shared library, then use this option to point to that JAR file. In addition, if you give `war.path` and also use the `-extractToDir` parameter, then any JAR files that are in the WAR file's manifest class-path is not added to the class path (since the WAR file has now been extracted by itself outside the EAR file in which it resides). Use `-additional.classpath` in this case to point to the necessary JAR files. Add the full path to needed resources, separated by your system-dependent path separator.

  **Example:** JspBatchCompiler -war.path c:\myproject\examples.war -additional.classpath c:\myJars\someJar.jar;c:\myClasses

  **Use-case:** Use this parameter to add to the class path JAR files and classes outside of your WAR file. At run time, these same JAR files and classes have to be made available through the standard WebSphere Application Server configuration mechanisms.

  **Default:** null

- **verbose**

  Specifies whether the batch compiler should generate verbose output while compiling the generated sources.

  **Example:** JspBatchCompiler -war.path c:\myproject\examples.war -verbose true

  **Use-case:** Set this parameter to true when you want to see Java compiler class loading and other messages.

  **Default:** false

- **deprecation**

  Indicates the compiler should generate deprecation warnings while compiling the generated sources.

  **Example:** JspBatchCompiler -war.path c:\myproject\examples.war -deprecation true

  **Use-case:** Set this parameter to true when you want to see Java compiler deprecation messages.

  **Default:** false

- **javaEncoding**

  Specifies the encoding that will be used when the .java file is generated, and when it is compiled by the Java compiler. When -javaEncoding is set, that encoding is passed to the java compiler via the -encoding argument. Note that encoding is not supported by Jikes.

  **Example:** JspBatchCompiler -war.path c:\myproject\examples.war -javaEncoding Shift-JIS

  **Use-case:** Set this parameter when the page encoding of your JSP pages is not UTF-8 compatible.

  **Default value:** UTF-8.

- **jdkSourceLevel**

This JSP engine parameter was introduced in WebSphere Application Server version 6.1 to support JDK 5. Use this parameter instead of the compileWithAssert parameter, although compile WithAssert still works in version 6.1.

The default value for this parameter is 16. This parameter requires regeneration of Java source. The following are jdkSourceLevel paramater values:

- **13** - This value will disable all new language features of JDK 1.4, JDK 5.0 and JDK 6.0.
- **14** - This value will enable the use of the assertion facility and will disable all new language features of JDK 5.0 and JDK 6.0.
- **15** - This value will enable the use of the assertion facility and will disable all new language features of JDK 6.0.
- **16** - This value will enable the use of the new features of JDK 6.0.

**Example:** JspBatchCompiler -war.path c:\myproject\examples.war -jdkSourceLevel 14

**Use-case:** Set this parameter when you want to enable or disable the language features of JDK 1.4 , JDK 5.0, and JDK 6.0

**Default value:** 16

- **compilerOptions**

  Specifies a list of strings to be passed on the Java compiler command. This is a space-separated list of the form "arg1 arg2 argn".

  **Example:** JspBatchCompiler -war.path c:\myproject\examples.war -compilerOptions " -bootclasspath <path>"

  **Use-case:** Use this parameter if you need Java compiler arguments other than verbose, deprecation and Assert facility support.

  **Default:** null

- **useJikes**

  Specifies whether Jikes should be used for compiling Java sources. NOTE: Jikes is not shipped with WebSphere Application Server.

  **Example:** JspBatchCompiler -ear.path c:\myproject\sampleApp.ear -useJikes true

  **Use-case:** Set this parameter to true in order for the batch compiler to use Jikes as the Java compiler.

  **Default value:** false

- **jsp.file.extensions**

  Specifies the file extensions to be processed by the batch compiler. This is a semicolon- or colon-separated list of the form "*.ext1;*.ext2:*.extn". Note that this parameter is not necessary for Servlet 2.4 web applications because the url-pattern property of the jsp-property-group elements in the deployment descriptor can be used to identify extensions that should be treated as JSP pages.

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -jsp.file.extensions *jspz;*.jspt

  **Use-case:** Use this parameter to add additional extensions to the be processed by the batch compiler.

  **Default:** null. See section, "JSP file extensions", in this topic for additional information.

- **log.level**

  Specifies the level of logging that is directed to the console during batch compilation. Values are SEVERE | WARNING | INFO | CONFIG | FINE | FINER | FINEST | OFF

  **Example:** JspBatchCompiler -enterpriseApp.name sampleApp -log.level FINEST

  **Use-case:** Set this parameter higher or lower to control logging output. FINEST generates the most output useful for debugging.

  **Default:** CONFIG

***Batch compiler ant task:***

The ant task **JspC** exposes all the batch compiler configuration options. It runs the batch compiler under the covers. It is backward compatible with the WebSphere Application Server 5.x version of the **JspC** ant task. The following table lists all of the ant task attributes and their batch compiler equivalents.

*Table 168. Ant task attributes and their batch compiler equivalents. JspC attributes and the equivalent batch compiler parameters.*

| JspC attribute | Equivalent batch compiler parameter |
|---|---|
| earPath | -ear.path |
| warPath | -war.path |
| src<br><br>Same as warPath, for backward compatiblity | -war.path |
| enterpriseAppName | -enterpriseapp.name |
| responseFile | -response.file |
| webmoduleName | -webmodule.name |
| fileName | -filename -config.root |
| configRoot | -config.root |
| cellName | -cell.name |
| nodeName | -node.name |
| serverName | -server.name |
| profileName | -profileName |
| extractToDir | -extractToDir |
| compileToDir<br><br>same as compileToDir, for backward compatibility | -compileToDir -compileToDir |
| compileToWebInf | -compileToWebInf |
| compilerOptions | -compilerOptions |
| recurse | -recurse |
| removeTempDir | -removeTempDir |
| translate | -translate |
| compile | -compile |
| forceCompilation | -forceCompilation |
| useFullPackageNames | -useFullPackageNames |
| trackDependencies | -trackDependencies |
| createDebugClassfiles | -createDebugClassfiles |
| keepgenerated | -keepgenerated |
| keepGeneratedclassfiles | -keepGeneratedclassfiles |
| usePageTagPool | -usePageTagPool |
| useThreadTagPool | -useThreadTagPool |
| classloaderParentFirst | -classloader.parentFirst |
| classloaderSingleWarClassloader | -classloader.singleWarClassloader |
| additionalClasspath | -additional.classpath |
| classpath<br><br>same as additionalClasspath, for backward compatibility | -additional.classpath |
| verbose | -verbose |
| deprecation | -deprecation |
| javaEncoding | -javaEncoding |
| compileWithAssert | -compileWithAssert |
| useJikes | -useJikes |
| jspFileExtensions | -jsp.file.extensions |
| logLevel | -log.level |
| wasHome | none |
| Classpathref | none |
| jdkSourceLevel | -jdkSourceLevel |

Below is an example of a build script with multiple targets, each with different attributes. The following commands are used to launch the script:

On Windows:

```
ws_ant -Dwas.home=%WAS_HOME% -Dear.path=%EAR_PATH% -Dextract.dir=%EXTRACT_DIR%
ws_ant jspc2 -Dwas.home=%WAS_HOME% -Dapp.name=%APP_NAME% -Dwebmodule.name=%MOD_NAME%
ws_ant jspc3 -Dwas.home=%WAS_HOME% -Dapp.name=%APP_NAME% -Dwebmodule.name=%MOD_NAME% -Ddir.name=%DIR_NAME%
```

On UNIX or i5/OS:

```
ws_ant -Dwas.home=$WAS_HOME -Dear.path=$EAR_PATH -Dextract.dir=$EXTRACT_DIR
ws_ant jspc2 -Dwas.home=$WAS_HOME -Dapp.name=$APP_NAME -Dwebmodule.name=$MOD_NAME
ws_ant jspc3 -Dwas.home=$WAS_HOME -Dapp.name=$APP_NAME -Dwebmodule.name=$MOD_NAME -Ddir.name=$DIR_NAME
```

Example build.xml file using the JspC task

```
<project name="JSP Precompile" default="jspc1" basedir=".">
 <taskdef name="wsjspc" classname="com.ibm.websphere.ant.tasks.JspC"/>
 <target name="jspc1" description="example using  a path to an EAR, and extracting the EAR to a directory">
  <wsjspc wasHome="${was.home}"
            earpath="${ear.path}"
            forcecompilation="true"
            extractToDir="${extract.dir}"
            useThreadTagPool="true"
            keepgenerated="true"

  />
 </target>
 <target name="jspc2" description="example using an enterprise app and webmodule">
  <wsjspc wasHome="${was.home}"
            enterpriseAppName="${app.name}"
            webmoduleName="${webmodule.name}"
            removeTempDir="true"
            forcecompilation="true"
            keepgenerated="true"

  />
 </target>
 <target name="jspc3" description="example using an enterprise app, webmodule and specific directory">
  <wsjspc wasHome="${was.home}"
            enterpriseAppName="${app.name}"
            webmoduleName="${webmodule.name}"
            fileName="${dir.name}"
            recurse="false"
            forcecompilation="true"
            keepgenerated="true"

  />
 </target>
</project>
```

***Pre-touch tool for compiling and loading JSP files:***

When enabled, the pre-touch mechanism causes all JavaServer Pages (JSP) files to be compiled within the web module for which they are configured. You can also configure some or all JSP files to be class loaded and JIT-compiled.

To enable the pre-touch mechanism, use Rational Application Developer to specify the following JSP attributes, which are Assembly Property Extensions for your web module:

- **prepareJSPs (Required)**

  When this attribute is present, all JSP files are compiled at application server startup. This activity runs in a separate thread, allowing the application server to finish other startup actions in parallel. The

numeric attribute value represents the minimum size in kilobytes that a JSP file must be in order to also be class loaded and JIT-compiled. The default is 0, which causes all JSP files to be class loaded and JIT-compiled.

**Note:** JSP file compilation is different from JIT compilation. JSP compilation generates bytecodes, whereas JIT translates the bytecodes into machine code at run time.

- **prepareJSPAttribute (Optional)**

  The pre-touch mechanism compiles and JIT-compiles JSP files by directly invoking the JSP service method, thus making the JSP file susceptible to incurring exceptions because it is called out of context. Such exceptions are avoided by immediately checking the value of this attribute, causing a quick exit from the service method when the JSP was prepared by this tool. This attribute value is added as a request parameter and is composed of alphanumeric characters that your JSP files do not expect to use during normal initiation.
- **prepareJSPThreadCount (Optional)**

  Set this numeric attribute to the number of threads that you would like this mechanism to start up to compile your JSP files. Since a thread makes use of just one processor, multi-processor systems may better utilize this pre-touch mechanism by specifying a value greater than 1. The default setting for this attribute is 1, representing the number of threads that are created to perform pre-touch processing for this web module.
- **prepareJSPClassload (Optional)**

  Set this attribute to either a whole number or the word *changed*. By entering *changed*, only those JSP filess that have been updated or not previously touched, for example, those JSP files that need to be converted from a `.jsp` file to a `.java` file, are class loaded. By entering a numerical value, for example, 1000, the pre-touch tool starts class loading at the 1000th JSP that it processes and all subsequent JSP files. This is convenient in the event that the application server is stopped when starting the pre-touch tool. You can then check the server logs to see how many JSP files have been processed and update the prepareJSPClassload value accordingly to avoid duplicating work. If a JSP file is not class loaded, it cannot be JIT compiled. As a result, if a JSP file does not satisfy the requirements of the prepareJSPClassload attribute, but satisfies the requirements of the prepareJSPs attribute, the JSP file is compiled if it has been updated, but is not class loaded or JIT compiled.

***Batch compiler class path:***

The batch compiler builds its class path as shown in the table below. When the batch compiler target is a web application archive (WAR) file and `war.path` is supplied, the configuration *additional.classpath* parameter is used to give extra class path information.

*Table 169. Batch compiler. Batch compiler target.*

| | **Batch compiler target** | | |
|---|---|---|---|
| Location added to class path | enterpriseapp.name | ear.path | war.path |
| WebSphere Application Server JAR files and classes | yes | yes | yes |
| JAR files listed in manifest class path for a web module | yes | yes | yes, when the target WAR is inside an EAR and *–extractToDir* is not used; otherwise, no. |
| Shared libraries | yes | no | no |
| Web module JAR files and classes | yes | yes | yes |
| *additional.classpath* parameter to batch compiler | no | no | yes |

## Global tag libraries (deprecated)

JavaServer Pages (JSP) tag libraries contain classes for common tasks such as processing forms and accessing databases from JSP files.

Tag libraries encapsulate, as simple tags, core functionality common to many web applications. The Java Standard Tag Library (JSTL) supports common programming tasks such as iteration and conditional processing, and provides tags for:

- manipulating XML documents
- supporting internationalization
- using Structured Query Language (SQL)

Tag libraries also introduce the concept of an expression language to simplify page development, and include a version of the JSP expression language.

A tag library has two parts - a Tag Library Descriptor (TLD) file and a Java archive (JAR) file.

***tsx:dbconnect tag JavaServer Pages syntax (deprecated):***

Use the <tsx:dbconnect> tag to specify information needed to make a connection to a database through Java DataBase Connectivity (JDBC) or Open Database Connectivity (ODBC) technology.

Support for tsx tags in the JavaServer Pages (JSP) engine are deprecated in WebSphere Application Server Version 6.0. Instead of using the tsx tags, you should use equivalent tags from the JavaServer Pages Standard Tag Library (JSTL).

The <tsx:dbconnect> syntax does not establish the connection. Use the <tsx:dbquery> and <tsx:dbmodify> syntax instead to reference a <tsx:dbconnect> tag in the same JavaServer Pages (JSP) file to establish the connection.

When the JSP file compiles into a servlet, the Java processor adds the Java coding for the <tsx:dbconnect> syntax to the servlet service() method, which means a new database connection is created for each request for the JSP file.

This section describes the syntax of the <tsx:dbconnect> tag.

```
<tsx:dbconnect id="connection_id"
    userid="db_user" passwd="user_password"
    url="jdbc:subprotocol:database"
    driver="database_driver_name"
    jndiname="JNDI_context/logical_name">
</tsx:dbconnect>
```

where:

- **id**

  Represents a required identifier. The scope is the JSP file. This identifier is referenced by the connection attribute of a <tsx:dbquery> tag.
- **userid**

  Represents an optional attribute that specifies a valid user ID for the database that you want to access. Specify this attribute to add the attribute and its value to the request object.

  Although the userid attribute is optional, you must provide the user ID. See <tsx:userid> and <tsx:passwd> for an alternative to hard coding this information in the JSP file.
- **passwd**

  Represents an optional attribute that specifies the user password for the userid attribute. (This attribute is not optional if the userid attribute is specified.) If you specify this attribute, the attribute and its value are added to the request object.

Although the passwd attribute is optional, you must provide the password. See <tsx:userid> and <tsx:passwd> for an alternative to hard coding this attribute in the JSP file.

- **url** and **driver**

  Respresents a required attribute if you want to establish a database connection. You must provide the URL and driver.

  The application server supports connection to JDBC databases and ODBC databases.

  – For a JDBC database, the URL consists of the following colon-separated elements: jdbc, the subprotocol name, and the name of the database to access. An example for a connection to the Sample database included with IBM DB2 is:

    ```
    url="jdbc:db2:sample"
    driver="com.ibm.db2.jdbc.app.DB2Driver"
    ```

  – For an ODBC database, use the Sun JDBC-to-ODBC bridge driver included in their Java2 Software Developers Kit (SDK) or another vendor's ODBC driver.

    The url attribute specifies the location of the database. The driver attribute specifies the name of the driver to use in establishing the database connection.

    If the database is an ODBC database, you can use an ODBC driver or the Sun JDBC-to-ODBC bridge. If you want to use an ODBC driver, refer to the driver documentation for instructions on specifying the database location with the url attribute and the driver name.

    If you use the bridge, the url syntax is `jdbc:odbc:`*`database`*. An example follows:

    ```
    url="jdbc:odbc:autos"
    driver="sun.jdbc.odbc.JdbcOdbcDriver"
    ```

    **Note:** To enable the application server to access the ODBC database, use the ODBC Data Source Administrator to add the ODBC data source to the System DSN configuration. To access the ODBC Administrator, click the ODBC icon on the Windows NT Control Panel.

- **jndiname**

  Represents an optional attribute that identifies a valid context in the application server Java Naming and Directory Interface (JNDI) naming context and the logical name of the data source in that context. The web administrator configures the context using an administrative client such as the WebSphere Administrative Console.

  If you specify the jndiname attribute, the JSP processor ignores the driver and url attributes on the <tsx:dbconnect> tag.

An empty element (such as <url></url>) is valid.

***dbquery tag JavaServer Pages syntax (deprecated):***

Use the <tsx:dbquery> tag to establish a connection to a database, submit database queries, and return the results set.

Support for tsx tags in the JavaServer Pages (JSP) engine are deprecated in WebSphere Application Server Version 6.0. Instead of using the tsx tags, you should use equivalent tags from the JavaServer Pages Standard Tag Library (JSTL).

The <tsx:dbquery> tag does the following:

1. References a <tsx:dbconnect> tag in the same JavaServer Pages (JSP) file and uses the information the tag provides to determine the database URL and driver. You can also obtain the user ID and password from the <tsx:dbconnect> tag if those values are provided in the <tsx:dbconnect> tag.
2. Establishes a new connection
3. Retrieves and caches data in the results object.
4. Closes the connection and releases the connection resource.

This section describes the syntax of the <tsx:dbquery> tag.

```
<%-- SELECT commands and (optional) JSP syntax can be placed within the tsx:dbquery. --%>
<%-- Any other syntax, including HTML comments, are not valid. --%>
<tsx:dbquery id="query_id" connection="connection_id" limit="value" >
</tsx:dbquery>
```

where:

- **id**

  Represents the identifier of this query. The scope is the JSP file. Use `id` to reference the query. For example, from the <tsx:getProperty> tag, use `id` to display the query results.

  The `id` is a tsx reference to the bean and can be used to retrieve the bean from the page contect. For example, if id is named mySingleDBBean, instead of using:
  – if (mySingleDBBean.getValue("UISEAM",0).startsWith("N"))

  use:
  – com.ibm.ws.webcontainer.jsp.tsx.db.QueryResults bean = (com.ibm.ws.webcontainer.jsp.tsx.db.QueryResults)pageContext. findAttribute("mySingleDBBean"); if (bean.getValue("UISEAM",0).startsWith("N")). . .

  The bean properties are dynamic and the property names are the names of the columns in the results set. If you want different column names, use the SQL keyword for specifying an alias on the SELECT command. In the following example, the database table contains columns named FNAME and LNAME, but the SELECT statement uses the `AS` keyword to map those column names to FirstName and LastName in the results set:

  ```
  Select FNAME, LNAME AS FirstName, LastName from Employee where FNAME='Jim'
  ```

- **connection**

  Represents the identifier of a <tsx:dbconnect> tag in this JSP file. The <tsx:dbconnect> tag provides the database URL, driver name, and optionally, the user ID and password for the connection.

- **limit**

  Represents an optional attribute that constrains the maximum number of records returned by a query. If this attribute is not specified, no limit is used. In such a case, the effective limit is determined by the number of records and the system caching capability.

- SELECT command and JSP syntax

  Represents the only valid SQL command, SELECT. The <tsx:dbquery> tag must return a results set. Refer to your database documentation for information about the SELECT command. See other articles in this section for a description of JSP syntax for variable data and inline Java code.

***dbmodify tag JavaServer Pages syntax (deprecated):***

The <tsx:dbmodify> tag establishes a connection to a database and then adds records to a database table.

Support for tsx tags in the JavaServer Pages (JSP) engine are deprecated in WebSphere Application Server Version 6.0. Instead of using the tsx tags, you should use equivalent tags from the JavaServer Pages Standard Tag Library (JSTL).

The <tsx:dbmodify> tag does the following:

1. References a <tsx:dbconnect> tag in the same JavaServer Pages (JSP) file and uses the information provided by that tag to determine the database URL and driver.

   **Note:** You can also obtain the user ID and password from the <tsx:dbconnect> tag if those values are provided in the <tsx:dbconnect> tag.
2. Establishes a new connection.
3. Updates a table in the database.
4. Closes the connection and releases the connection resource.

This section describes the syntax of the <tsx:dbmodify> tag.

```
<%-- Any valid database update commands can be placed within the DBMODIFY tag. -->
<%-- Any other syntax, including HTML comments, are not valid. -->
<tsx:dbmodify connection="connection_id">
</tsx:dbmodify>
```

where:

- **connection**

  Represents the identifier of a <tsx:dbconnect> tag in this JSP file. The <tsx:dbconnect> tag provides the database URL, driver name, and (optionally) the user ID and password for the connection.
- Database commands

  Represents valid database commands. Refer to your database documentation for details

In the following example, a new employee record is added to a database. The values of the fields are based on user input from this JavaServer Pages (JSP) file and referenced in the database commands using the <tsx:getProperty> tag.

```
<tsx:dbmodify connection="conn" >
insert into EMPLOYEE
    (EMPNO,FIRSTNME,MIDINIT,LASTNAME,WORKDEPT,EDLEVEL)
values
('<tsx:getProperty name="request" property=request.getParameter("EMPNO") />',
'<tsx:getProperty name="request" property=request.getParameter("FIRSTNME") />',
'<tsx:getProperty name="request" property=request.getParameter("MIDINIT") />',
'<tsx:getProperty name="request" property=request.getParameter("LASTNAME") />',
'<tsx:getProperty name="request" property=request.getParameter("WORKDEPT") />',
<tsx:getProperty name="request" property=request.getParameter("EDLEVEL") />)
</tsx:dbmodify>
```

***tsx:getProperty tag JavaServer Pages syntax and examples (deprecated):***

The <tsx:getProperty> tag gets the value of a bean to display in a JavaServer Pages (JSP) file.

**Note:** Support for tsx tags in the JavaServer Pages (JSP) engine are deprecated in WebSphere Application Server Version 6.0. Instead of using the tsx tags, you should use equivalent tags from the JavaServer Pages Standard Tag Library (JSTL).

This IBM extension of the Sun JSP <jsp:getProperty> tag implements all of the <jsp:getProperty> function and adds the ability to introspect a database bean created using the IBM extension <tsx:dbquery> or <tsx:dbmodify>.

**Note:** You cannot assign the value from this tag to a variable. The value, generated as output from this tag, displays in the browser window.

This section describes the syntax of the <tsx:getProperty> tag:

```
<tsx:getProperty name="bean_name"
  property="property_name" />
```

where:

- **name**

  Represents the name of the bean declared by the id attribute of a <tsx:dbquery> syntax within the JSP file. Refer to the <tsx:dbquery> article for an explanation. The value of this attribute is case-sensitive.
- **property**

  Represents the property of the bean to access for substitution. The value of the attribute is case-sensitive and is the locale-independent name of the property.

Tag example:

```
<tsx:getProperty name="userProfile" property="username" />
```

***tsx:userid and tsx:passwd tag JavaServer Pages syntax (deprecated):***

With the <tsx:userid> and <tsx:passwd> tags, you do not have to hard code a user ID and password in the <tsx:dbconnect> tag.

**Note:** Support for tsx tags in the JavaServer Pages (JSP) engine are deprecated in WebSphere Application Server Version 6.0. Instead of using the tsx tags, you should use equivalent tags from the JavaServer Pages Standard Tag Library (JSTL).

Use the <tsx:userid> and <tsx:passwd> tags to accept user input for the values and then add that data to the request object. You can access the request object with a JavaServer Pages (JSP) file, such as the *JSPEmployee.jsp* example that requests the database connection.

You must use <tsx:userid> and <tsx:passwd> tags within a <tsx:dbconnect> tag.

This section describes the syntax of the <tsx:userid> and <tsx:passwd> tags.

```
<tsx:dbconnect id="connection_id"
    <font color="red"><userid></font>
    <tsx:getProperty name="request" property=request.getParameter("userid") />
    <font color="red"></userid></font>
    <font color="red"><passwd></font>
    <tsx:getProperty name="request" property=request.getParameter("passwd") />
    <font color="red"></passwd></font>
    url="protocol:database_name:database_table"
    driver="JDBC_driver_name">
</tsx:dbconnect>
```

where:

- **<tsx:getProperty>**

  Represents the syntax as a mechanism for embedding variable data.
- **userid**

  Represents a reference to the request parameter that contains the user ID. You must add the parameter to the request object that passes to this JSP file. You can set the attribute and its value in the request object, using an HTML form or a URL query string to pass the user-specified request parameters.
- **passwd**

  Represents a reference to the request parameter that contains the password. Add the parameter to the request object that passes to this JSP file. You can set the attribute and its value in the request object, using an HTML form or a URL query string, to pass user-specified values.

***tsx:repeat tag JavaServer Pages syntax (deprecated):***

The <tsx:repeat> tag repeats a block of HTML tagging.

Support for tsx tags in the JavaServer Pages (JSP) engine are deprecated in WebSphere Application Server Version 6.0. Instead of using the tsx tags, you should use equivalent tags from the JavaServer Pages Standard Tag Library (JSTL).

Use the <tsx:repeat> syntax to iterate over a database query results set. The <tsx:repeat> syntax iterates from the start value to the end value until one of the following conditions is met:

- The end value is reached.
- An exception is thrown.

If an exception of the types **ArrayIndexOutOfBoundsException** or **NoSuchElementException** is created before a block completes, output is written only for the iterations up to and not including the iteration during which the exception was created. All other exceptions results in no output being written for that tag instance.

This section describes the syntax of the <tsx:repeat> tag:

```
<tsx:repeat index="name" start="starting_index" end="ending_index">
</tsx:repeat>
```

where:

- **index**

  Represents an optional name used to identify the index of this repeat block. The scope of the index is NESTED. Its type must be integer.
- **start**

  Represents an optional starting index value for this repeat block. The default is 0.
- **end**

  Represents an optional ending index value for this repeat block. The maximum value is 2,147,483,647.

  If the value of the end attribute is less than the value of the start attribute, the end attribute is ignored.

**Combining tsx:repeat and tsx:getProperty JavaServer Pages tags (deprecated)**

Support for tsx tags in the JavaServer Pages (JSP) engine are deprecated in WebSphere Application Server Version 6.0. Instead of using the tsx tags, you should use equivalent tags from the JavaServer Pages Standard Tag Library (JSTL).

The following code snippet shows you how to code these tags:

```
<tsx:repeat>
<tr>
    <td><tsx:getProperty name="empqs" property="EMPNO" />
    <tsx:getProperty name="empqs" property="FIRSTNME" />
    <tsx:getProperty name="empqs" property="WORKDEPT" />
    <tsx:getProperty name="empqs" property="EDLEVEL" />
    </td>
</tr>
</tsx:repeat>
```

***Example: Using tsx:repeat JavaServer Pages tag to iterate over a results set (deprecated):***

The <tsx:repeat> tag iterates over a results set. The results set is contained within a bean. The bean can be a static bean, for example, a bean created by using the IBM WebSphere Studio database wizard, or a dynamically generated bean, for example, a bean generated by the <tsx:dbquery> syntax.

**Note:** Support for tsx tags in the JavaServer Pages (JSP) engine are deprecated in WebSphere Application Server Version 6.0. Instead of using the tsx tags, you should use equivalent tags from the JavaServer Pages Standard Tag Library (JSTL).

The following table is a graphic representation of the contents of a bean called, *myBean*:

*Table 170. Graphic representation of myBean.. myBean contents.*

| | col1 | col2 | col3 |
|---|---|---|---|
| row0 | friends | Romans | countrymen |
| row1 | bacon | lettuce | tomato |
| row2 | May | June | July |

Some observations about the bean:

- The column names in the database table become the property names of the bean. The <tsx:dbquery> section describes a technique for mapping the column names to different property names.
- The bean properties are indexed. For example, `myBean.get(Col1(row2))` returns `May`.

- The query results are in the rows. The <tsx:repeat> tag iterates over the rows, beginning at the start row.

The following table compares using the <tsx:repeat> tag to iterate over a static bean, versus a dynamically generated bean:

*Table 171. Static Bean and <tsc:repeat> Bean example. Use this table to compare the two beans.*

| Static Bean Example | <tsx:repeat> Bean Example |
|---|---|
